Abstract Second level therapeutic manoeuvres for controlling intracranial hypertension (ICH) proposed by the European Brain Injury Consortium and the American Association of Neurological Surgeons include barbiturates, moderate hypothermia and more recently the decompressive craniectomy (DC). In most patients, ICP can be maintained below 25 mmHg after a DC. However, the exact effect of DC on brain oxygenation (PtiO2) still unclear. From our point of view the PtiO2 monitoring with the probe located in the healthy area of the most severely damaged cerebral hemisphere is not only an important tool for timing craniectomy in the future but also for evaluating the therapeutic effectivity of DC.

¿Mejora la craniectomía descompresiva otros parámetros además de la PIC? Efectos de la craniectomía descompresiva en la presión tisular

Resumen Las medidas terapéuticas de segundo nivel para el control de la hipertensión intracraneal que propone el European Brain Injury Consortium y la American Association of Neurological Surgeons son los barbitúricos, la hipotermia moderada o más recientemente la craneectomía descompresiva (CD). En la mayoría de los pacientes la Presión Intracraneal se mantiene por debajo de 25 mmHg tras la CD. Sin embargo, el efecto de la CD sobre la monitorización de la presión tisular de oxígeno cerebral (PtiO2) no está claro. Desde nuestro punto de vista, la monitorización de la PtiO2 con el catéter colocado en área aparentemente sana del hemisferio más dañado no solo es una herramienta útil para la indicación del momento de la CD sino también para evaluar la efectividad terapéutica de la misma.

Intracranial hypertension (ICH) without space-occupying lesions remains the most frequent cause of death and disability following a serious brain condition, particularly (but not exclusively) among trauma patients. Approximately 10-15% of all patients with severe cranioencephalic traumatism (CET) suffer ICH refractory to the maximum clinical management measures. In this situation, the intensivist and neurosurgeon face the dilemma of having to decide which second-level therapeutic options can be used: high barbiturate doses, moderate hypothermia or decompressive craniotomy (DC), as proposed by the European Brain Injury Consortium and the American Association of Neurological Surgeons (AANS).

Despite the recommendations of the Brain Trauma Foundation on the use of barbiturates, the updated Cochrane review concludes that although such treatment is able to reduce intracranial pressure (ICP), there is no evidence that such reduction implies lesser mortality or improved outcome among the survivors. Moreover, the decrease in ICP was associated to a drop in arterial pressure in at least one out of every four cases.

While prophylactic moderate hypothermia was discarded after the study published by Cifton, there are data suggesting that it could be used as a second level measure for the control of ICH, though there are no definitive conclusions in this regard.

Thus, DC possibly may represent a reasonable second level option which both the intensivist and neurosurgeon may prescribe for the treatment of refractory ICH in critical neurological patients when there are no space-occupying lesions.

Although over 240 articles related to DC have been published in the last 10 years (100 of them in the last two years), no randomized, prospective and controlled study (class I evidence) has been made to date in adults, demonstrating the benefit of DC in relation to final patient outcome. Nevertheless, recently many articles offering class III evidence have been published, together with some non-randomized, prospective single-center studies, and the results regarding the control of refractory ICH were found to be better with DC than in its absence.

Considering the above, neurosurgeons and intensivists have shown renewed interest in cranial decompression and aperture of the dura mater for controlling ICH refractory to first-level management measures, despite the fact that the Cochrane review conducted by Sahuquillo et al. on the use of DC in ICH refractory to treatment among brain injury patients concluded that there are no data to either confirm or refute the effectiveness of such treatment in adults.

In most of the analyzed studies on decompressive craniotomy, the authors monitored post-decompressive craniotomy ICP in the decompressed hemisphere. In this region the brain expands, shifting the pressure-volume curve to the right. This would explain the decrease in ICP recorded in the majority of the studies made. In our experience, commented in a recent review published in 2009, where ICP was monitored in 28 patients, the median ICP prior to DC was 33 mmHg (range 28-45). In 22 of these patients (78.6%) the pressure dropped to < 25 mmHg after DC, and the outcome proved unfavorable in the 6 patients in which the ICP remained > 25 mmHg.

Due to the increase in brain blood volume after DC, and since the brain is no longer contained within a closed space, some reviews on the management of ICH propose that the threshold for the management of ICP should be lowered to 15 mmHg in these patients. In addition, the Cambridge group has suggested the consideration of lower values of mean arterial pressure and cerebral perfusion pressure (CPP), for although cerebral adaptability improves after DC, vasoconstrictive blood vessel reactivity to increased transmural pressure is affected - thus causing increases in pressure to imply progressive increases in ICP.

The measurement of local brain oxygenation using a Clark-type polarographic catheter implanted in the brain (PtO$_2$) is common practice in many critical neurological patient units, according to the latest guidelines published by the Brain Trauma Foundation. Since 1999 in our hospital we have systematically monitored PtO$_2$ together with ICP in all patients with severe CET. We have analyzed such monitoring in over 300 patients with severe CET, and always attempt to position the catheter in the apparently healthy area of the most damaged hemisphere in the case of evacuated expansive lesions; in the most affected hemisphere in the case of diffuse lesions; and in the right frontal lobe in the case of diffuse lesions without apparent differences in damage between the two hemispheres.

Recent articles have described improved brain oxygenation (PtO$_2$) after cranial decompression. In our experience with 28 patients, PtO$_2$ monitoring was carried out before and after DC. Of these subjects, 19 underwent PtO$_2$ monitoring with the electrode placed in the apparently healthy area in the CAT scan of the most damaged hemisphere (i.e., the side of the craniotomy), while in two cases monitoring of the side opposite the hemicraniotomy was performed, and in the remaining three patients bilateral monitoring was carried out. After decompression, a significant increase in PtO$_2$ was recorded (9.7 ± 7.06 mmHg) with the catheter placed in the apparently healthy area of the hemicraniotomy hemisphere versus the PtO$_2$ recorded on the contralateral side, which even dropped to 1.4 ± 3.8 mmHg on average (p < 0.001). Three patients remained with initial PtO$_2$ values in the range of brain ischemia and did not increase to the normal levels of PtO$_2$ measured on the craniotomy side after DC. These patients all suffered brain death. Other studies have described multiple monitoring involving ICP, CPP, microdialysis and PtO$_2$ simultaneously before and after DC - with improvements not only in ICP, CPP and PtO$_2$, but also in the parameters obtained at microdialysis, such as glucose concentration and the lactate / pyruvate ratio. In addition, while involving a limited number of patients (n = 5), the study published by Reitmeier et al. found that although ICP decreased in all subjects after DC, only those showing normalization of PtO$_2$ and of the biochemical parameters as a result of microdialysis presented a favorable outcome. These studies do not specify the precise positioning of the PtO$_2$ catheters or of microdialysis. At present, we are analyzing the changes in PtO$_2$ before and after DC only when the catheter was positioned before and after DC on the craniotomy side in 33 patients, and the preliminary results presented at the XI Congress of the Euroacademy of Multidisciplinary Neurotraumatology (www.emn2010.com) indicate that the patients showing a greater persistent PtO$_2$
increment above the brain hypoxia threshold (20 mmHg) and after DC showed an improved Glasgow Outcome Scale (GOS) score 6 months after trauma compared with those individuals with significantly lesser increments or with persistent values below the brain hypoxia threshold.

The indication of DC has always been centered on refractory ICH, independently of the presence or absence of brain hypoxia. However, once the brain pressure has been freed as a result of the craniotomy, and particularly after apertura of the dura mater, hyperemia develops in the areas affected before decompression and which have a strong oxygen demand. Furthermore, the blood vessels that were compressed now fill again, and dilatation occurs secondary to vessel paralysis as a result of the metabolic changes. This increase in regional brain blood volume may increase the edema and necrosis in the zone despite normal ICP values.

Such decompressive hyperemia was studied by Yamakami et al. using SPECT technology. These authors found perfusion to increase in the decompressed brain region after a few minutes, reaching a maximum after one week; posteriorly, after approximately one month, perfusion normalized in coincidence with patient improvement. The authors added that hyperperfusion occurred particularly when DC was performed too late. In this same line, Yoshida et al. reported that such hyperperfusion may protect the brain from hypoxemic cell damage, as demonstrated by improvement in brain lactate and potassium clearance via xenon (Xe) CT and spectroscopic magnetic resonance imaging. This in turn would result in a decrease in cytotoxic edema, thereby avoiding the drop in cerebral blood flow, which posteriorly would give rise to elevations in ICP.

Therefore, and independently of the reductions in ICP, the normalization of PtiO2 after DC described above could afford another beneficial effect in relation to patient outcome.

Then why not indicate DC in cases of brain hypoxia with moderately elevated ICP (20-25 mmHg) instead of exclusively waiting for ICH > 25-30 mmHg when the first level management options have been exhausted?

In our experience, DC could be a therapeutic option in the case of brain hypoxia (PtiO2 < 10 mmHg in the apparently healthy area on the CAT scan) with moderate intracranial hypertension, when CPP has been optimized, with hemorrhage levels > 11 g/dL and once all possible systemic causes of cerebral hypoxia have been discarded (hypoxemia, hypotension, sepsis, hypocapnia, etc.).

Considering the above, we feel that PtiO2 monitoring in a healthy area of the most damaged cerebral hemisphere may be useful not only for indicating the timing of decompressive craniotomy, but also for evaluating its effectiveness.
