Sinusal reversion of supraventricular tachyarrhythmias after propofol administration. A case series*

Reversión de taquiarritmias supraventriculares tras la administración de propofol. Serie de casos

Dear Editor,

Propofol is a widely used phenol derivative with sedative and hypnotic properties. Among its cardiovascular effects we may find the dose-dependent reduction of pre-load, post-load, and myocardial contractility as the most widely known ones, although other effects have come up recently such as its potential protective role in the ischaemia-reperfusion damage, its influence on the cardiac conduction system, and its capacity to modify the action potential phases since it can act on the ionic channels of the myocyte membrane. These effects provide this drug with antiarrhythmic properties, even though the evidence and clinical experience on this field is still scarce. This is why we decided to conduct a retrospective analysis on the clinical histories of patients who got medical assistance in our hospital and presented with supraventricular tachyarrhythmias, and who restored their sinus rhythm after the administration of propofol without the need for any further manoeuvres. We designed a protocol for the collection of data aimed at homogenizing all information, and brought it to our hospital ethics committee that would later approve it (HCB Code/2016/0751, approval date October 24th, 2016).

Six patients were included in this analysis between January 2010 and April 2016. The age range of most women (83.33 per cent) was between 35 and 70 years of age (53.3 ± 13.53). The arrhythmias detected were atrial fibrillation (AFib) (50 per cent), intranodal re-entrant tachycardia (INRT) (33.3 per cent), and atrial flutter (AF) (16.7 per cent). Nearly all cases presented at the ER with symptoms associated with any of these arrhythmias, being palpitations and chest pains the most common symptoms of all. Only one case happened in the ophthalmology operating room but the patient remained asymptomatic (Table 1).

The cases of AFib were interpreted as episodes of paroxysm AFib, which is why pharmacological cardioversion was attempted with amiodarone (they received one IV bolus of 300 mg, and then continuous perfusion of 900 mg in 24 hours). The cases of INRT received carotid massages plus IV adenosine (up to 24 mg) before making any decision to perform electrical cardioversions.

The administration of propofol in the cases that presented with AFib and INRT attempted to initiate a process

---

of deep sedoanalgesia in order to perform an electric cardioversion procedure once other antiarrhythmic measures had failed. When it comes to the female patient with AF, the hypnotic drug was administered as an inducer to be able to perform the peribulbar ophtalmic blockade. The average dose administered was 45.8 mg ± 16.4 mg (range 20–75 mg). The patients with INRT received lower doses (20–40 mg) compared to those with paroxysmic AFib (50–75 mg). All of them received the hypnotic drug through one IV bolus and reversion to sinus rhythm occurred within the first two minutes after the administration of the drug. The 6 cases were discharged from the hospital in sinus rhythm after a period of 4 ± 1.3 hours. None of the patients came back to the hospital days later with a new episode of arrhythmia in the 6-month follow-up that we conducted. These data are shown in Table 1.

There are isolated reports of reversion to sinus rhythm of supraventricular tachyarrhythmias after the administration of propofol in adult patients. Kannan and Sherwood reported the case of a sixty-eight year old patient with a history of ischaemic heart condition who presented with atrial flutter that could be reversed after the administration of one IV bolus of 100 mg of propofol. Similarly, and in the same journal, Magaldi et al. reported one of the six cases collected in the analysis where they talked about the possible antiarrhythmic properties of the drug in a seventy year old patient with reversion of AF after the administration of 40 mg de propofol. Similarly, Choi and Jee describe 2 cases of women with AF who received both remifentanil and propofol through target-controlled infusion during surgical acts (propofol dose of 3.7 and 2.5 μg/ml), achieving reversion to sinus rhythm 10 and 30 minutes after initiating the perfusion, respectively. The average dose administered to our patients was 45 mg. We should mention that the wide variability of the doses administered, also mentioned in the reference and in our patients might be due to a prior use of antiarrhythmic drugs, to the anthropometric characteristics of the subjects, and to the physiopathogenic mechanism of the arrhythmias (re-entrant, abnormal automaticity, etc.).

Although the cardiovascular effects of alkylphenol are well known since it was first introduced, the mechanisms through which it acts upon the cardiac conduction system are still under study today. In electrophysiological studies of patients with AFib, a decrease in the P-wave dispersion when homogenizing and regularizing the spreading compared to the atrial wall depolarization could be confirmed, being this effect even more relevant when the AFib was paroxysmic. On the other hand, in experimental models of myocardial ischaemia-reperfusion, propofol has proven beneficial effects since it reduces the trend towards action potential shortening in ischaemic regions, which in turn leads to a reduced incidence of functional re-entrant tachyarrhythmias. These intrinsic antiarrhythmic effects of propofol seem to be mediated by its proven inhibitory effects on the potassium channels responsible for the repolarization phases 1 and 3 ($h_{Ko}$, and $I_{KUR}$, and ATP-sensitive, respectively), and the calcium channels involved in repolarization phase 2 ($I_{CaL}$).

The parasympathetic predominance may be one of the mechanisms that condition the reduction of arrhythmias due to abnormal automaticity, as it is the case with myocardial ischaemia.

AF: atrial flutter; AFib: atrial fibrillation; INRT: intranodal re-entrant tachycardia.

Table 1: Characteristics of patients.
while propofol was being administered, the arrhythmia just ceased. Lastly, the prior administration of amiodarone in cases of AFib may have had an influence on the reversion after the administration of propofol, although initially (after the total dose of 1200 mg of amiodarone in 24 hours) the goal of sinus rhythm control was not accomplished.

As a conclusion and with the evidence available today, we the authors believe that prospective and comparative trials should be conducted in order to assess the real effectiveness of this drug in the context of stable supraventricular tachyarrhythmias that do not respond to other medications.

Effect of single-dose of tolvaptan in neurocritical patients with hyponatremia due to syndrome of inappropriate antidiuretic hormone secretion

Efecto de una dosis única de tolvaptán en pacientes neurocríticos con hiponatremia debido a SIADH

Dear Editor,

Hyponatremia constitutes the most common electrolyte abnormality found in patients with acquired brain injury, being present in up to 20% of patients with traumatic brain injury (TBI) and 50% of patients with subarachnoid hemorrhage (SAH). In most cases, the underlying cause of euvoicmic hyponatremia in brain injured patients is the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). In this syndrome, an abnormal water/sodium handling is associated with an osmotic gradient that promotes the shift of water into brain cells, thereby worsening cerebral edema and resulting in deteriorating neurological condition with seizures, coma, increased intracranial pressure end eventually death. An appropriate correction of hyponatremia was associated with increased survival.

In the recent years, tolvaptan, an orally active, selective, nonpeptide antagonist that blocks arginine vasopressin from binding to V2 receptors of the distal nephron inducing the excretion of electrolyte-free water (the so-called ‘aquaretic effect’) showed it effectiveness in the treatment of hyponatremia in randomized controlled trials, but its use in neurocritically ill patients remains limited. Concerns with the potential risk of overtreatment and secondary osmotic demyelinating syndrome (ODS) arose, although the incidence of overtreatment can be even higher when using the commonly accepted 3% hypertonic saline. When tolvaptan is used, initial doses of 7.5 or 15 mg are recommended. Some authors recommend its use as a treatment of SIADH induced hyponatremia when first line therapies including fluid restriction have failed.

In this report, we studied the effects of a single dose of tolvaptan in hyponatremic neurocritically ill patients. The study was approved by our Hospital Research Committee. The need of informed consent was waived due to the descriptive and retrospective nature of the study. All patients fulfilled the following definition of SIADH:

Plasma sodium < 135 mEq/L
Plasma osmolality < 280 mOsm/kg of water
