Catheter-related bloodstream infections (CRBSI) constitute an important cause of hospital-acquired infection associated with morbidity, mortality, and cost. The aim of these guidelines is to provide updated recommendations for the diagnosis and management of CRBSI in adults. Prevention of CRBSI is excluded. Experts in the field were designated by the two participating Societies (the Spanish Society of Infectious Diseases and Clinical Microbiology and [SEIMC] and the Spanish Society of Spanish Society of Intensive and Critical Care Medicine and Coronary Units [SEMICYUC]). Short-term peripheral venous catheters, non-tunneled and long-term central venous catheters, tunneled catheters and hemodialysis catheters are covered by these guidelines. The panel identified 39 key topics that were formulated in accordance with the PICO format. The strength of the recommendations and quality of the evidence were graded in accordance with ESCMID guidelines. Recommendations are made for the diagnosis of CRBSI with and without catheter removal and of tunnel infection. The document establishes the clinical situations in which a conservative diagnosis of CRBSI (diagnosis without catheter removal) is feasible. Recommendations are also made regarding empirical therapy, pathogen-specific treatment (coagulase-negative staphylococci, Staphylococcus aureus, Enterococcus spp., Gram-negative bacilli, and Candida spp.), antibiotic lock therapy, diagnosis and management of suppurative thrombophlebitis and local complications.

Diagnóstico y tratamiento de la bacteriemia relacionada con catéter: guía de práctica clínica de la Sociedad Española de Enfermedades Infecciosas y Microbiología Clínica (SEIMC) y de la Sociedad Española de Medicina Intensiva, Crítica y Unidades Coronarias (SEMICYUC)

La bacteriemia relacionada con catéteres (BRC) es una causa importante de infección hospitalaria y se asocia con elevados morbimilidad, mortalidad y costes. El objetivo de esta guía de práctica clínica es proporcionar recomendaciones actualizadas para el diagnóstico y tratamiento de la BRC en pacientes adultos. De este documento se excluye la prevención de la BRC. Expertos en la materia fueron designados por las dos Sociedades participantes (Sociedad Española de Enfermedades Infecciosas y Microbiología Clínica y Sociedad Española de Medicina Intensiva, Crítica y Unidades Coronarias). Los catéteres venosos periféricos a corto plazo, los catéteres venosos centrales no tunelizados y de largo plazo, los catéteres tunelizados y los catéteres de hemodiálisis están incluidos en estas guías. El panel identificó 39 temas clave que fueron formulados de acuerdo con el formato PICO. La fuerza de las recomendaciones y la calidad de la evidencia se clasificaron de acuerdo con las directrices de la ESCMID. Se dan recomendaciones para el diagnóstico de BRC con extracción de catéter y sin él, y de la infección en túnel. El documento establece las situaciones clínicas en que es factible un diagnóstico conservador de CRBSI (diagnóstico sin retirada de catéter). También se dan recomendaciones respecto a la terapia empírica, el tratamiento específico según el patógeno identificado (estafilococos coagulasa-negativos, Staphylococcus aureus, Enterococcus spp., bacilos graminomortales y Candida spp.), la terapia con sellado del catéter y el diagnóstico, así como tratamiento de la tromboflebitis supurativa y las complicaciones locales.

Introduction: justification and aims

Intravascular devices have become an essential component of modern medicine for the administration of intravenous fluids, medication, blood products and parenteral nutrition and for monitoring hemodynamic status and providing hemodialysis. According to national data supplied by the study of the prevalence of nosocomial infections in Spain (EPINE), it is estimated that about 70% of patients admitted to Spanish hospitals will wear one of these devices at some point during their stay.1 Local or systemic infections represent one of the main associated complications.2 The incidence of catheter-related infections varies considerably depending on the type and intended use, the insertion site, the experience and training of the individual who places the catheter, the frequency with which the catheter is accessed, duration of catheter placement, the characteristics of the patient, and the use of proven prevention strategies. Catheter-related bloodstream infections (CRBSIs) are among the most frequent infections acquired in hospital. Current estimates are that between 15% and 30% of all nosocomial bacteremias are catheter-related.3 CRBSIs have significant associated morbidity, incur increased hospital costs,4 estimated at approximately 18,000 euros per episode, and length of stay.5 Attributable mortality ranges between 12% and 25%.6 In recent years, there has been a remarkable increase in our knowledge of the epidemiology of CRBSI and of the most appropriate methodological tools for diagnosis, management and prevention. The vast amount of information accumulated and the inherent complexity of this type of infection make it necessary to sort and analyze the available information. At the same time, there are few current guidelines available on this topic. The last Spanish catheter-related infections guidelines were published in 2004.7 The aim of this new guide is to update recommendations for the diagnosis and management of catheter-related bloodstream infections. This document targets only microbiological diagnosis and antimicrobial therapy; other aspects of infection management and prevention are therefore excluded. Only adult patients with these infections are covered.

Methods

The two participating Societies (the Sociedad Española de Enfermedades Infecciosas y Microbiología Clínica and the Sociedad Española de Medicina Intensiva, Crítica y Unidades Coronarias) nominated three coordinators for this project (FC, JGM and JLdP: a microbiologist, an intensivist, and an infectious disease physician). This coordinating group selected the rest of the members of the panel, including microbiologists, intensivists, and infectious disease physicians. The Scientific Committees of both Societies approved their proposal. The present Statement was written following the SEIMC guidelines for consensus statements (www.seimc.org) as well as the recommendations of the Agree Collaboration (www.agreecollaboration.org) for evaluating the methodological quality of clinical practice guidelines. The strength of the recommendations and quality of the evidence were graded in accordance with ESCMID guidelines (Table 1).

The coordinating group identified 39 key topics that were formulated in accordance with the PICO format defining the population, intervention, comparator, and outcome of interest. These key questions were approved by the Scientific Committees of both Societies and then distributed to the different members of the panel (2 or 3 questions each) for further development. The coordinating group wrote the first draft based on the sections submitted by each participant, which was then sent to the panel for critical review. Before its final approval, the document was published on the intranet of both Societies and left open to suggestions and comments from members. All authors and coordinators of the Statement have agreed the contents of the document and the final recommendations. A summary of these recommendations is available in the Supplementary Electronic Material.

Catheter-related bloodstream infection diagnosis (Table 2)

General aspects

When should catheter-related bloodstream infection be suspected?

CRBSI should be clinically suspected if the patient has fever, chills or hypotension with signs of infection proximal to insertion sites of peripheral venous cannulae or on the skin overlying the subcutaneous tunnel of a tunneled catheter.8 Several circumstances should increase suspicion that a given episode of bacteremia is catheter-related. The most obvious one is a patient with local signs of infection at the catheter. In addition, bloodstream infections are often caused by microorganisms that colonize the skin, such as Staphylococcus aureus, coagulase-negative staphylococci, Corynebacterium spp., Bacillus spp., Candida spp., among others. CRBSI should also be considered in settings of persistent or recurrent blood cultures for given microorganisms.8 Clinical suspicion of CRBSI should also arise in patients with intravenous catheters who have focal infections known to be caused by the hematogenous spread of bacteria (i.e., septic emboli); this is the case in endocarditis or suppurative thrombophlebitis, particularly if caused by Staphylococcus spp. or Candida spp. in patients with venous catheters. Septic emboli secondary to a CRBSI are more frequently found in the lungs,9 although virtually any organ can be affected by septic metastasis arising from an infected catheter.10,11

RECOMMENDATIONS

1. CRBSI should be suspected in patients with intravenous catheters and fever, chills or other signs of sepsis, even in the absence of local signs of infection, and especially if no alternative source is identified (A-III).
2. Clinical suspicion of CRBSI should also arise in patients with intravenous catheters with metastatic infections caused by hematogenous spread of microorganisms (i.e., septic emboli) (A-III).
3. Persistent or recurrent bacteremia caused by microorganisms that colonize the skin in patients with intravenous catheters should lead to CRBSI suspicion (A-III).

**How is complicated catheter-related bloodstream infection defined?**

There are several factors associated with worse outcomes in patients with CRBSI and identifying these risk factors can help in the management of those patients. There is no universally accepted definition of complicated CRBSI. Endocarditis is one of the main CRBSI-associated complications with a prolonged therapy that requires catheter removal. Suppurative thrombophlebitis also makes CRBSI complicated, as do metastatic foci of infection, which usually require prolonged therapy and catheter removal. Local complications, such as tunnel infection or a port abscess, even in the absence of septic thrombophlebitis, require catheter removal and so complicate a CRBSI. Systemic severity (septic shock) in patients with suspected CRBSI is another circumstance that should lead to prompt catheter removal. Non-resolving fever or bacteremia (≥72 h) should lead to a detailed reassessment of the patient in order to rule out local or distant infectious complications and so should be considered complicated CRBSI. It is very important to closely monitor immunocompromised hosts with CRBSI for possible treatment failure.

**RECOMMENDATIONS**

1. Patients diagnosed with CRBSI and with endocarditis, suppurative thrombophlebitis, septic metastasis, extraluminal infections, septic shock, non-resolving CRBSI, or immunocompromised patients should be categorized as complicated CRBSI (A-III).
2. Non-resolving fever or bacteremia (≥72 h) should lead to a detailed reassessment of the patient in order to rule out local or distant infectious complications and so should be considered complicated CRBSI (A-III).

**Diagnosis without catheter withdrawal (conservative diagnosis)**

**How should blood cultures be taken?**

Because the aim of a blood culture is to detect true bacteremia and avoid contamination leading to unnecessary treatment, a proper diagnostic methodology is needed. This is particularly important when catheter-related bacteremia is suspected, because the common etiologic agents are also the most frequent contaminants.

Conventional blood cultures are currently performed using commercial systems with automated detection of growth. These systems consist of an aerobic and an anaerobic bottle, considered as one blood culture set. Some studies show a sensitivity of <80% for one blood culture set and >99% for 3 or more culture sets. To ensure optimal detection of bacteremia, the volume of blood is the essential factor. The Clinical and Laboratory Standards Institute (CLSI) recommends therefore that a blood volume of at least 20 ml be inoculated into each of 2 blood culture sets (two bottles per set) taken from different venipuncture sites.

Blood must be obtained using an aseptic methodology to reduce the risk of contamination to less than 3% of all blood culture sets, which is considered to be the acceptable range. The venipuncture should be performed after disinfecting the skin. The three key factors when choosing the antiseptic are: antimicrobial spectrum, method of application, and duration of antimicrobial effect. The most commonly used disinfectants are alcohol-, chlorhexidine- and iodine-based products. A recent meta-analysis of 6 randomized control trials concluded that: (1) overall, alcohol-based products seemed to be superior to non-alcohol-based solutions, and (2) solutions containing a combination of alcohol and chlorhexidine showed significant reductions in contaminated blood cultures compared with aqueous povidone-iodine. The most widely studied concentration is 2% chlorhexidine gluconate in isopropyl alcohol. On the other hand, a recent study showed that choice of antiseptic agent did not impact contamination rates when the blood cultures were collected by a phlebotomy team. Perhaps the single most important aspect is the use of proper technique, which includes time required to perform the procedure and allowing enough time for the disinfectant to exert its antimicrobial effect. Alcohol and chlorhexidine products require 30 s to dry, whereas povidone iodine preparations require 1.5–2 min. No studies have evaluated the effect of disinfecting catheter access hubs before drawing the blood samples, although it seems to be a rational intervention aimed at minimizing risk of contamination.

The timing of blood culture collection may vary. Although most blood culture systems have different methods of minimizing the effect of antibiotics, the samples should
be obtained, if at all possible, before antibiotic therapy is started. Blood cultures obtained from intravascular catheters are associated with higher sensitivity and negative predictive values. In patients with suspected CRBSI, two sets of blood cultures should be taken, one from a peripheral vein and the other from the catheter hub. For multiple-lumen venous catheters, several studies suggest that blood cultures be drawn from all lumens (i.e., the same volume from each lumen) to establish a diagnosis of CRBSI. Omitting a culture of samples from one or more lumens is associated with failing to detect a considerable number of CRBSI episodes.

</tbody>
</table>
Once drawn, the blood should be immediately inoculated into the blood culture bottles, which should then be appropriately marked (peripheral vein, catheter, etc.) and promptly and simultaneously incubated in the automated machine, in order to interpret the results on the basis of time to positivity of each blood culture set. Because the rubber caps are not sterile, they are usually disinfected with an alcohol solution, which must be dried before inoculation. Since the incidence of true anaerobic bacteremia is low, it may be preferable to inoculate the optimal volume of blood into the aerobic bottle first, and then the remaining volume into the anaerobic bottle.

**RECOMMENDATIONS**

1. Blood cultures should be obtained using an aseptic technique and before the initiation of antimicrobial therapy (A-I).
2. Skin preparation for obtaining blood samples drawn percutaneously should be performed with proper techniques, including the time to perform the procedure and leaving adequate time for the disinfectant to take effect (A-I). Alcohol-containing products are associated with low rates of contamination. Alcohol-chlorhexidine solutions reduce blood culture contamination more efficiently than aqueous povidone-iodine (A-I).
3. Two pairs of blood cultures should be drawn in patients with suspected CRBSI, one from a peripheral vein and the other from the catheter (A-I).
4. For multiple-lumen venous catheters, samples should be obtained from all lumens (A-II).

**How should conventional blood cultures be interpreted?**

Identification of the microorganism is considered crucial for interpreting the significance of the result. Propionibacterium spp., Bacillus spp., and most Corynebacterium spp. almost always mean contamination. Contamination is defined as the isolation of an organism in a blood culture that is not present in the patient’s bloodstream. Unfortunately, some of the microorganisms that frequently contaminate blood cultures are also common causes of CRBSI, such as coagulase-negative staphylococci, which is the leading cause of CRBSI. Other organisms that cause bacteremia, such as Staphylococcus aureus and Enterococcus spp., can also be detected as contaminants, albeit in a low percentage of cases. In the case of skin commensals, at least 2 positive blood cultures with an identical strain are required for them to be considered a cause of bacteremia.

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) is one of the most widely evaluated new technologies for the rapid microbial identification of blood culture isolates. Although the performance of MALDI-TOF-based identification varies depending on the enrichment and purification methods used, this technology has shown high sensitivity and specificity for rapid identification of microbes in positive blood cultures. MALDI-TOF has some limitations associated with the identification of some Gram-positive microorganisms (Streptococcus spp.), non-fermenting Gram-negatives, and non-albicans Candida species, although its use in the clinical setting could improve time to identification of microorganisms, time to effective therapy and time to optimal antimicrobial therapy. Detecting the actual time to positivity of each blood culture is considered critical to the diagnosis of CRBSI. Several studies have confirmed that measuring the differential time to positivity (DTP) of blood cultures obtained from a central venous catheter and a peripheral vein is highly diagnostic for suspected CRBSI. Biot et al. reported that a DTP cut-off limit of 120 min had 94% sensitivity and 94% specificity for catheter-related infection, and 96.4% sensitivity and 100% specificity for catheter-related sepsis. Other studies showed similar results for the same cut-off value, with sensitivities ranging from 72% to 96.4% and specificities between 90.3% and 95%. Raad et al. showed that a DTP of ≥ 120 min was associated with a 81% sensitivity and 92% specificity for short-term catheters (<30 days) and 93% sensitivity and 75% specificity for long-term catheters (>30 days). Although this diagnostic test has been implemented in routine clinical practice, some authors have reported that DTP is not useful for diagnosis of CRBSI in medical surgical intensive care units. These differences can be attributed to the definition of CRBSI used or to the type of microorganism causing the CRBSI. A recent report suggested that a DTP of ≥ 120 min was the optimal cut-off point for diagnosis of Candida spp. CRBSI (85% sensitivity and 82% specificity), except for Candida glabrata. However, in a study of catheter-related candidaemia (CRC) that included mainly Candida albicans and Candida parapsilosis, Bouza et al. found that a DTP of ≥ 120 min had high sensitivity (94.7%) but low specificity (40%). In general, the accuracy of the DTP method requires accurately tracking how long it takes the blood cultures from the source (central venous catheter vs. peripheral vein) to become positive. The method also relies on the cultures being placed in the automated machine at the same time.

For suspected CRBSI, detection of the identical microorganism in blood cultures obtained via peripheral venipuncture and the suspected catheter was recently evaluated as a means of diagnosing CRBSI without catheter removal. Although most laboratories use antimicrobial susceptibility testing and biochemical identification to establish identity without using molecular techniques, which seems to be the most practical way to compare isolates, the possibility of polyclonal infection should always be considered, as several studies have demonstrated that polyclonal infections are probably more common than previously suspected.

**RECOMMENDATIONS**

1. Positivity of blood cultures obtained through the catheter ≥ 120 min before those obtained from a peripheral vein with the same microorganism is highly suggestive of CRBSI. An optimal DTP cut-off for the diagnosis of catheter-related candidaemia has not been established (A-II).
2. The interpretation of DTP should consider adherence to the procedural technique used and the type of microorganism (A-II).
3. Rapid microbial identification by MALDI-TOF MS from a positive blood culture significantly reduces time to identification of microorganisms and has clinical impact on the management of patients with suspected bloodstream infection (A-II).
How should quantitative blood cultures be taken and interpreted?

The quantitative methodology is based on lysing red blood cells with different detergents, centrifugation (i.e., lysis-centrifugation) and inoculating the sediment into different culture media and in different atmospheres. This system has shown better results than conventional methods in terms of detection times and specificity, but is relatively complex and the sample must be processed within 20–30 min of inoculation of the blood into the tube. There are no specific guidelines for the procedure of obtaining blood cultures, so that the recommendations for conventional blood cultures above also apply to quantitative blood cultures, 15,16,25–27,31 except for inoculation into the bottle. In the lysis-centrifugation system, 10 ml of blood is inoculated into the lysis tube, which contains the specific amount of detergent for this volume. After inoculation, the blood and detergent should be gently mixed before centrifugation is performed. Another currently used method for diagnosing CRBSI is the pour plate method. 16 Briefly, for each quantitative blood culture, 1–3 ml of blood is mixed with 20 ml of previously melted brain heart infusion agar at 56 °C in Petri plates, then the plates are incubated aerobically for 4 days at 35–37 °C.

The number of blood cultures required is similar to conventional blood cultures. For diagnosis of CRBSI, several authors have demonstrated that a differential colony count that is (5–10 times) greater for the intravascular catheter blood culture than the peripheral vein culture is indicative of CRBSI. 42,58-61 In a meta-analysis performed by Safrar et al., 62 the differential quantitative blood culture (DQBC) was the best approach for diagnosing CRBSI without catheter removal, with a pooled sensitivity of 0.79 (95% CI: 0.74, 0.84), and pooled specificity of 0.99 (95% CI: 0.98, 1.0). There is some controversy about the cut-off point of DQBC. A study that evaluated different cut-off points for paired quantitative blood cultures for the diagnosis of CRBSI showed that the DQBC was not useful with short-term central venous catheters (CVCs), although in long-term CVCs, DQBCs of 2:1 or greater, or 5:1 or greater were sensitive, but associated with low specificity and positive predictive values. 40 Quantitative blood cultures are labor intensive and expensive, which makes them less practicable for routine use.

RECOMMENDATION

1. A quantitative blood culture with a colony count 3 times greater in a sample drawn through a catheter than from the peripheral vein supports a diagnosis of CRBSI (A-II).

What particular aspects should be considered for the diagnosis of CRBSI in patients on hemodialysis?

For patients without a functioning vascular access, central venous catheters (CVC) have become an acceptable means of vascular access for hemodialysis (HD), although their clinical usefulness is severely limited by potential infectious complications. 63-65 The relative risk of a CV causing CRBSI in HD patients is estimated to be approximately 10 times higher than the risk of bacteremia in patients with an arteriovenous fistula or graft. 53,60,66 In HD patients, particularly in the outpatient setting, it is difficult to meet the standard microbiological criteria of paired quantitative blood cultures and differential time to positivity to confirm diagnosis of CRBSI. The limitations of the standard diagnostic criteria for CRBSI include the following:

1. Obtaining peripheral blood cultures may be impossible in up to 40% of HD patients, either because their peripheral veins have been exhausted or because of the need to avoid venipuncture in veins intended for the future creation of a dialysis fistula or graft. 25,66-69
2. If blood cultures are drawn during the dialysis session when systemic blood is circulating through the catheter, there is no significant difference between peripheral and catheter blood culture results, so that peripheral sampling can be omitted. 67-69
3. In the absence of concurrent blood cultures from the catheter and a peripheral vein, there is a risk that a positive blood culture corresponds to a source of infection other than the catheter. 65,68
4. In the outpatient setting, longer preinoculation due to excessive time for transportation may lead to a false-negative DTP. 25,69

RECOMMENDATION

1. Whenever possible, paired blood samples from the CVC and a peripheral vein should be obtained for CRBSI diagnosis in hemodialysis patients (A-II).

2. Peripheral blood samples should be obtained from veins that are not intended for future creation of dialysis fistula or grafts. The veins of the hand for outpatients and hand or femoral veins for hospital inpatients should be used to obtain peripheral blood cultures (A-III).

3. If a blood sample cannot be drawn from a peripheral vein, two separate samples should be drawn, 10–15 min apart, through the CVC or the dialysis circuit connected to the catheter (B-II).

What other conservative techniques may be used for diagnosis of CRBSI?

Conservative methods for the diagnosis of CRBSI include endoluminal brushing, superficial cultures of the skin around the insertion site and catheter hubs, and the Gram stain with acridine orange leukocyte cytopsin (AOLC) test. 42,43,70-72 Endoluminal brushing, a method of sampling the internal surface of the catheter, showed high sensitivity (95–100%) and specificity (84–89%) in two studies 5,7,73 although the procedure is impractical and unreliable and major side-effects have been reported, such as cardiac arrhythmias and embolization with subsequent bacteremia. 56 Superficial cultures (semiquantitative cultures of skin around the catheter insertion site and catheter hubs) have also been proposed for the diagnosis of CRBSI, 43 based on a sensitivity and specificity of 78% and 92%, respectively. It has been suggested that superficial and peripheral blood cultures be combined to screen for CRBSI, reserving DQBC as a more specific technique for confirmation. Other authors have also reported on the Gram stain-AOLC test as a rapid method for diagnosis of CRBSI. 70 The method requires two 50 μL samples of catheter blood. After several steps, including the use of cytopsin technology, a monolayer of leukocytes and microorganisms is placed on two slides, then stained with either
acridine orange or Gram stain, and viewed by ultraviolet and light microscopy, respectively. The authors reported a 96% sensitivity and 92% specificity. In the meta-analysis by Safdar et al., the overall sensitivity and specificity of the ALOC test were 72% and 91%, respectively. Generally speaking, these methods have not been validated by other authors and are not widely used in clinical laboratories. Table 2 gives a brief summary of these conservative methods and those requiring catheter removal.

**RECOMMENDATIONS**

1. Endoluminal brushing of the internal surface of the catheter may be useful for diagnosis of CRBSI. However, the procedure is impractical and major side-effects have been reported (C-III).
2. Semi-quantitative cultures of skin around the catheter insertion site and catheter hubs with ≥ 15 CFU may be indicative for CRBSI. These procedures must be combined with peripheral blood culture (B-II).
3. Gram stain-acridine orange leukocyte cytoplasm (AOLC) of catheter blood may be used as a rapid method for diagnosis of CRBSI. The presence of any microorganisms in a minimum of 100 high-powered fields may be indicative of CRBSI (B-II).

**What is the value of molecular techniques for the diagnosis of CRBSI?**

Most molecular techniques for diagnosis of CRBSI without catheter withdrawal are performed directly on blood samples drawn through catheters. Various molecular methods have been applied to many different patient populations. A 16S rDNA analysis of blood drawn through vascular access devices in patients with hematologic disorders had a 100% positive predictive value for CRBSI. Other authors used pulsed-field gel electrophoresis (PFGE) to confirm CRBSI caused by coagulase-negative staphylococci (CoNS) in patients with neutropenia. Most studies are based on real-time PCR, such as LightCycler® Septifast or Gene Xpert® which are demonstrated to be a very complementary diagnostic tool for blood cultures, especially in patients receiving antibiotics. There is very little data about the use of molecular techniques with samples other than blood to confirm a CRBSI episode.

Although direct molecular detection techniques for detecting microorganisms in the blood and other samples are a promising approach for improving patient management and outcome by streamlining the diagnosis of CRBSI, they are still currently unable to replace the traditional culture and remain expensive and time-consuming.

**RECOMMENDATION**

1. There is not enough information to recommend implementing molecular techniques in clinical practice for CRBSI diagnosis (C-II).

**Diagnosis of CRBSI with catheter withdrawal**

*When should a catheter tip be sent for culture?*

Diagnosis of CRBSI requires establishing the presence of a bloodstream infection (see section *How should blood cultures be taken?*) and demonstrating that the infection is related to the catheter. As a general recommendation, a catheter culture should only be obtained when a CRBSI is suspected, thus avoiding unnecessary cultures. Several factors should be taken into consideration when determining whether the catheter should be removed: the type of catheter, ease of new catheter insertion, immune status, the severity of the underlying illness of the patient, and the presence and severity of sepsis.

**RECOMMENDATION**

1. Catheter cultures should only be obtained when CRBSI is suspected (A II).

*How should a catheter be sent to and processed in the Microbiology Laboratory?*

After pulling the catheter, its tip should be cut to a length of 5 cm approximately, under sterile conditions and avoiding contact with the patient’s skin, and then placed in a dry, sterile container for transport. The catheter tip should be stored at 4–8°C while transport to the laboratory is arranged.

The most widely used laboratory technique is the semi-quantitative method described by Maki, in which the catheter segment is rolled across a blood agar plate using sterile forceps. After overnight incubation, the number of colony-forming units (CFUs) is counted. One limitation of this method is that it mainly detects colonization on the external surface of the catheter. This is more of a concern with long-term catheters, where luminal colonization more frequently leads to bloodstream infections.

In 1980, Cleri described a quantitative culture method to improve the detection of microorganisms progressing inside the catheter lumen. Quantitative cultures of the endolumen were obtained by immersing the catheter segment in 2–10 ml of tryptic soy broth (TSB), then flushing it three times with a syringe. The broth was serially diluted 100-fold. 0.1 ml of each dilution was streaked onto sheep blood agar and the number of CFUs counted after incubation.

Brun-Bruisson et al. simplified Cleri’s technique by placing the catheter segments into a test tube with 1 ml of sterile distilled water. After vortexing for 1 min, 0.1 ml of the suspension is plated onto blood agar. Other modifications of quantitative endoluminal cultures include a quantitative sonication technique, in which the catheter tip is placed in 10 ml of TSB and sonicated for 1 min. 0.1 ml of the sonicated broth and a 1:100 dilution of the broth are plated onto blood agar and the number of colony-forming units counted.

In order to distinguish between colonization on the internal and external surfaces of the catheter, Liñares et al. used the semiquantitative method for culturing the catheters, then a modified quantitative technique, flushing each catheter lumen with 2 ml of TSB, which was then serially diluted and plated.

All quantitative methods are time-consuming, whereas the simplicity of semiquantitative techniques has contributed to their widespread use in clinical microbiology laboratories. Several prospective studies have compared Maki’s semiquantitative technique with quantitative methods (sonication and vortexing) for detection of CRBSI and concluded that the three methods exhibited similar reliability, although Maki’s semiquantitative technique was simpler to use.
The predictive values of quantitative or semiquantitative methods may vary depending on the type and location of the catheter, the culture methodology used, and the source of catheter colonization. For example, skin-colonizing microorganisms are more likely to colonize the external surface of a recently inserted catheter, so that Maki’s semi-quantitative method would be very sensitive for identifying this colonization. By contrast, a catheter that has been in place for more than a week could be colonized intraluminally via the hub, rendering the roll plate method less sensitive. In this case, methods that obtain samples for culture from both internal and external surfaces are more sensitive.

RECOMMENDATIONS

1. The most reliable diagnostic methodologies for catheters sent to culture are the semiquantitative (roll plate) or quantitative (vortex or sonication methods) (A-II).
2. Qualitative cultures (culture of the catheter tip by broth immersion) are unreliable for distinguishing between contamination and infection, and are not therefore suitable for the diagnosis of CRBSI (A-II).

How should the results of catheter cultures be interpreted?

A semiquantitative catheter cultures discriminate between catheters as the cause of infection and non-significant colonization. The catheter is considered to be the source of infection if growth from a culture of the catheter tip is \( \geq 15 \) CFU, whereas \(<15\) CFU with no associated clinical signs is considered to be catheter colonization. \(^{91}\) The cut-off point of \( \geq 15 \) CFU is significantly associated with clinical signs and bacteremia, with a 76% specificity. \(^{92}\) Subsequent studies have validated the semiquantitative culture technique for evaluating catheter-related infections. \(^{98,99}\) There is no established cut-off point for mycobacteria and fungi.

For quantitative catheter cultures (flushing the internal surface and vortexing), the cut-off point has been established at \( 10^3 \) CFU/segment, based again on its association with bacteremia in CRBSI. Colony counts of less than \( 10^3 \) CFU are considered intermediate, possible contamination, or the early stages of colonization. \(^{91,92}\) For quantitative cultures based on sonication, a cut-off point of \( >10^3 \) CFU was established to discriminate between catheter infection and catheter colonization. \(^{93}\) In general, semiquantitative and quantitative cultures give comparable results, although the semiquantitative procedure is easier and faster in practice. \(^{27,100}\)

RECOMMENDATIONS

1. The presence of more than 14 CFU per plate by semiquantitative culture (roll-plate) is indicative of significant catheter colonization (A-II).
2. A count of \( 10^3 \) CFU/segment or more using quantitative culture methods based on vortexing or flushing the internal surface reflects significant catheter colonization (A-II).
3. Counts above \( 10^2 \) CFU/segment for quantitative culture methods based on sonication indicate significant catheter colonization (A-II).

How should a subcutaneous reservoir be processed?

Venous access devices (VADs) are widely used for long-term access to the vascular system, mainly in cancer patients. The diagnosis and management of CRBSI also includes a recommendation to perform a qualitative culture of the port reservoir contents as well as a semiquantitative culture of the catheter tip if VAD-related bloodstream infection (VAD-RBSI) is suspected. This has been thoroughly studied in patients with suspected VAD-RBSI by comparing VAD cultures with blood cultures obtained before removal. In all studies, the catheter tip cultures failed to detect several VAD-RBSI episodes, whereas cultures of the endoluminal content (thrombotic material) had better predictive value. \(^{101-104}\)

Bouza et al. assessed the validity values of cultures obtained from multiple sites of 223 VADs that had been withdrawn for some reason and confirmed that the rate of VAD colonization improved when they not only obtained cultures from the catheter tip and the inside of the port, but also from the sonication fluid used to obtain microorganisms from the external surface of the port. \(^{105}\) In addition, del Pozo et al. assessed the yield from the septum of 240 VAPs after sonication. The latter procedure showed the highest sensitivity and specificity (78% and 93%, respectively) for diagnosing VAD colonization with a cut-off of 110 CFU/ml. \(^{106}\)

These recent findings will probably have an impact on the routine laboratory processing of pulled VADs, since confirmation of VAD-RBSI requires performing cultures of the catheter tip, and the inner and outer surfaces of the port. There is no consensus statement for thresholds for VAD cultures.

RECOMMENDATION

1. Venous access devices removed for suspected CRBSI should be sent to the microbiology laboratory. Routine processing should include a combination of cultures from different parts of the VAD, including a culture after septum sonication and semiquantitative catheter cultures (B-II).

What is the present value of molecular techniques for the diagnosis of CRBSI after catheter removal?

Diagnosis of CRBSI requires confirmation that the microorganisms isolated from blood and catheter tip cultures are phenotypically identical. A recent study using quantitative PCR for the detection of CoNS suggested that the role of the catheter as a source of bacteremia may be overestimated. \(^{107}\) Indeed, the conventional microbiological procedures used to diagnose CoNS CRBSI performed badly when compared with an evaluation by PFGE of different morphotypes of CoNS isolated from catheter tip and blood cultures. \(^{108}\) By contrast, using microsatellite markers, the genotypes of Candida isolates recovered from blood cultures and catheter tips were a match in 91% of patients studied. \(^{109}\)

Due to its low sensitivity, 16S rRNA polymerase chain reaction (PCR) has not managed to replace the conventional culture and there are at present no data about the application of molecular methods to non-tunneled catheters. On the other hand, the application of 16S rRNA PCR using endoluminal samples increased detection of venous access device-related bloodstream infection (VAD-RBSI) in patients undergoing antibiotic therapy by 21.1%. \(^{110}\)
In summary, molecular methods have the potential to improve diagnosis of CRBSI in patients undergoing antibiotic therapy, although these techniques have not been standardized.

**RECOMMENDATION**

1. 16S rRNA PCR could be performed with septum sonication fluid to rule out or confirm VAD-RBSI in patients undergoing antibiotic therapy (C-III).

**Diagnosis of local signs of infection**

*What samples should be taken and how should they be interpreted when an insertion site infection is suspected?*

Insertion site infections are characterized by signs of inflammation, including induration, erythema, warmth, and pain or tenderness within 2 cm of the catheter insertion site. They may also be associated with other signs and symptoms of infection, such as fever or purulent discharge from the insertion site, with or without a concomitant bloodstream infection.6,111 A microbiologically documented insertion site infection is defined as exudate with a positive culture at the catheter insertion site.6,111 The sensitivity and positive predictive value of local inflammation for the diagnosis of CRBSI is shown to be very low.112 When catheter infection is suspected and there is exudate at the catheter insertion site, the exudate should be sent for Gram staining, routine culture, and additional culture for fungi as indicated when assessing immunocompromised patients.25 Blood cultures should also be drawn.6,111,112

In the absence of local signs of infection, the results of several studies suggest that semi-quantitative cultures of swabs of skin taken from around the insertion site and surface cultures from the internal surface of the catheter hubs may be useful for ruling out catheter colonization and infection, and so avoiding unnecessary catheter withdrawals.43,81,113–115 For skin samples, a dry cotton swab should be rubbed over a 2 cm² area around the insertion site. For hub samples a small alginate swab should be introduced into each hub and rubbed repeatedly against its inner surface.43 Semi-quantitative growth of <15 CFU from both the insertion site and the catheter hub enables CRBSI to be ruled out,43,113 although surface cultures show very low specificity and positive predictive value. Combining a semiquantitative culture of the subcutaneous tract with a hub swab culture improves specificity and positive predictive values.116

VAD-related infection should be suspected if a patient exhibits signs of a local infection, such as pain or erythema at the implant site.104 A local complicated infection is defined as infection of the tunnel or pocket, with extended erythema or induration (more than 2 cm), purulent collection, skin necrosis and spontaneous rupture and drainage. Clinical signs of local infection, such as redness or purulent exudate, have high specificity but low sensitivity.101,104 A recent study showed that 23% of patients with VAD-related infection had local signs of infection.117 In such cases, a culture of purulent fluid and/or necrotic tissue surrounding the port is required. Blood culture from peripheral veins should also be performed in order to rule out CRBSI.

**RECOMMENDATIONS**

1. When there is exudate at the catheter insertion site, it should be sent for Gram staining and culture. Blood cultures should also be drawn (A-III).

2. In patients with suspected catheter-related infection but negative superficial cultures (growth of <15 CFU from both the insertion site and catheter hub cultures), the possibility of infection can reasonably be ruled out (B-II).

**Catheter related bloodstream infection treatment**

The main antimicrobial drug and dosage regimens that should be used for CRBSI are shown in Table 3.

*When can a catheter be retained until blood cultures are available?*

Two studies found no differences in outcome when early CVC removal was compared with a watchful waiting strategy for suspected CRBSI in patients with non-tunneled catheters.118–120 These studies excluded patients with neutropenia, solid organ or hematologic malignancy, immunosuppressive drugs or radiation therapy, organ transplants, intravascular foreign bodies, hemodynamic instability, suppuration or frank erythema/induration at the insertion site, as well as bacteremia or fungemia. One of these ICU studies was a randomized single-center clinical trial118 and the other was prospective, observational, and multicenter.119 In the multicenter study, CRBSI was confirmed in only 12% of patients and there was no difference in mortality between immediate and late removal of the CVC. Another randomized trial demonstrated that, with critically ill patients, the DTP method makes it possible to use a watchful waiting strategy up to definitive diagnosis of CRBSI.121 It should be noted that catheter exchange is not without its risks, and severe complications, although fortunately uncommon, can occur.122

**RECOMMENDATION**

1. Immediate removal of the CVC is not routinely recommended when CRBSI is suspected in patients who are hemodynamically stable, without immunosuppressive therapy, intravascular foreign bodies or organ transplantation, no suppuration at the insertion site or bacteremia/fungemia, (A-I).

*When is it safe to perform a catheter exchange over a guidewire?*

A CVC replacement can be inserted by percutaneous venipuncture at a new site or by using the Seldinger over-the-guidewire technique. A meta-analysis of 12 randomized controlled trials (RCT)122 that evaluated guidewire exchange versus new-site insertion found non-significant differences between the two for the prevention of CRBSI. Guidewire exchange was associated with fewer mechanical complications (8 RCTs, relative risk = 0.48, 95% confidence interval = 0.12–1.91) but also a higher rate of catheter colonization (9 RCTs, relative risk = 1.26, 95% confidence interval = 0.87–1.84), catheter exit-site infections (5 RCTs, relative risk = 1.52, 95% confidence interval = 0.34–6.73)
Table 3 The main antimicrobial drug and dosage regimens that should be used for catheter-related infections.

</table>

Note that doses of the drugs are not adjusted for renal or hepatic function.

and catheter-related bacteraemia (9 RCTs, relative risk = 1.72, 95% confidence interval = 0.89–3.33). A study of 1598 CVCs in critically ill patients showed that over-the-guidewire exchange was associated with the development of CRBSI. On the other hand, inserting tunneled hemodialysis catheters using elective guidewire exchange from non-tunneled catheters was not associated with a higher incidence of catheter infections, and venous access was preserved in these high-risk patients.

Guidewire exchange is not indicated for patients with documented catheter infections or CRBSI. Using guidewire-assisted exchange to replace a malfunctioning catheter is an option if there is no evidence of infection at the catheter site and new percutaneous venipuncture is not recommended because of a high risk of complications (difficult venous access, bleeding diathesis).

**RECOMMENDATIONS**

1. Routine replacement of a CVC by guidewire exchange is not recommended because this strategy is associated with a higher risk of associated infectious complications. (B-II)
2. Guidewire exchange of a CVC is contraindicated in patients with documented catheter-related infections. (A-II)
3. Guidewire exchange should be restricted to patients with very difficult venous access (i.e., extensive burns, morbid obesity, or severe coagulopathy) and without documented catheter infection (B-II). In this case, a meticulous aseptic technique and a culture of the catheter tip are mandatory. (A-III)
4. If the catheter tip culture is positive, the new line, inserted over a guidewire, should be re-placed via a new direct venipuncture. (C-III)

*What should be done if the catheter tip culture is positive, but the blood cultures are negative?*

There is very limited data about the clinical implications of a positive CVC tip culture with negative blood cultures taken at the time of catheter removal.

Two retrospective studies concluded that an intravascular catheter colonized with *S. aureus* is a risk factor for subsequent *S. aureus* CRBSI. Antibiotic therapy initiated within 24 h of catheter removal significantly reduced the risk for subsequent *S. aureus* bacteraemia (SAB).

Another retrospective multicenter study showed a lower incidence of septic complications after the removal of a colonized catheter in patients with early antibiotic treatment (13% vs. 4%) (OR = 4.2; 95% CI = 1.1–15.6). In that study, exit-site infection was also a risk factor for the development of *S. aureus* CRBSI (OR = 3.39; 95% CI = 1.9–9.34). A meta-analysis of four retrospective studies yielded a pooled OR of 5.8 (95% CI = 2.6–13.2) for SAB when antibiotic therapy was not initiated. The number needed to treat to prevent 1 episode of SAB was 7.4. Conversely, a more recent retrospective study concluded that administration of early antistaphylococcal therapy had no impact on outcome, which was defined as *S. aureus* infection within 3 months of catheter withdrawal or death with no obvious cause. The only factor independently associated with a poor outcome were clinical signs of sepsis at the time the catheter was removed (OR = 20.8; 95% CI = 2.0–206.1). A retrospective study showed that the incidence of SC was 2.5% and that administration of antifungals...
was not protective in 55% of patients. Another study however showed that the risk of infectious complications following catheter removal was higher when Candida spp. were involved (7.7%) than in the case of bacterial infection (1.8%) and initiating antifungal therapy was suggested for all patients with positive catheter tip cultures and negative blood cultures.

No clear recommendations can be given if the catheter is colonized with other microorganisms. The decision should be individualized, although antimicrobial therapy would be justified only in patients with septic shock and no other obvious explanation for the clinical picture.

**RECOMMENDATIONS**

1. Antibiotic treatment (i.e., 5–7 days) should be given to patients with catheter tip cultures positive for S. aureus and negative blood cultures if the patient shows systemic or local infection (B-II).
2. In non-neutropenic patients or those without valvular heart disease, the presence of a catheter tip culture positive for Candida spp. and negative or unavailable blood cultures should be assessed on an individual basis before starting systematic antifungal treatment. Antifungal treatment should not be prescribed for patients without systemic signs of infection (B-II).
3. No clear recommendations can be given for catheters colonized with other microorganisms (C-III).

**Empirical antimicrobial therapy**

*What is the empirical antimicrobial therapy for CRBSI?*

The initial choice of antimicrobial should be based on an assessment of the risk factors for infection, the severity of the clinical picture and the likely pathogens associated with the specific intravascular device. Fig. 1 summarizes the recommended empirical approach for a patient with a high index of suspicion for CRBSI.

Patients with S. aureus CRBSI are at high risk for haemogenous metastasis, especially when the catheter cannot be removed and/or antibiotic treatment is not appropriate. As most CoNS are methicillin-resistant, the choice of empirical therapy should include antibiotics with activity against these strains. Vancomycin is the most commonly prescribed antimicrobial for CoNS and methicillin-resistant S. aureus (MRSA) bacteremia in recent decades. Studies comparing the efficacy and safety of glycopeptides (i.e., vancomycin vs. teicoplanin) for *Staphylococcus* spp. (including MRSA) bacteremia have not observed significant differences, although clinical isolates of *Staphylococcus epidermidis* and *Staphylococcus haemolyticus* have been reported with reduced susceptibility to teicoplanin.

Vancomycin is associated with lower clinical success rates for MRSA bacteremia with MICs $\geq 1.5$ mg/l (measured by E-test) in a case–control study focusing on cases of MRSA bloodstream infection with a vancomycin MIC $\geq 1.5$ mg/l (measured by E-test), a higher survival rate was observed in the patient group treated with daptomycin. Multivariate analysis confirmed that renal impairment and previous therapy with vancomycin were associated with significantly higher clinical failure. The impact on the outcome of bacteremia caused by CoNS with vancomycin MIC $\geq 1.5$ mg/l (measured by E-test) is an unresolved issue.

Previous studies have indicated that vancomycin is inferior to beta-lactams (i.e., cefazolin or oxacillin) for the treatment of methicillin-susceptible *Staphylococcus aureus* (MSSA) bloodstream infections. This would justify the inclusion of a beta-lactam in the empirical treatment of any suspected case of CRBSI. A recent study compared beta-lactams and vancomycin for empirical and definitive therapy of MSSA bloodstream infections among 5787 patients from 122 hospitals. Patients who received definitive therapy with a beta-lactam had a 35% lower mortality compared with patients who received vancomycin (HR = 0.65; 95% CI = 0.52–0.80) after controlling for other factors.

Daptomycin is a lipopeptide antibiotic with in vitro activity against Gram-positive bacteria and is also more bactericidal than vancomycin. The only randomized trial that has compared daptomycin with vancomycin or a beta-lactam concluded that daptomycin was noninferior to vancomycin. In a recent cohort study including 579 episodes of bacteremia caused by MRSA, no significant differences were observed in the mortality of patients treated with vancomycin or daptomycin (OR = 1.42 [95% CI = 0.83–2.44]). However, a recent study analyzing the efficacy of daptomycin in 40 cancer patients treated for Gram-positive CRBSI (including S. aureus) compared with a historical control group of 40 patients treated with vancomycin confirmed faster bacteriological eradication and clinical resolution in the daptomycin group.

In a randomized clinical trial of skin-structure infection and CRBSI with S. aureus, including MRSA, linezolid and its comparators showed similar efficacy for CRBSI. A meta-analysis of 5 randomized controlled trials of MRSA bacteremia observed that linezolid was noninferior to vancomycin.

**RECOMMENDATIONS**

1. If CRBSI is suspected, antimicrobial therapy should be started as soon as possible with a bactericidal agent active against S. aureus and CoNS, especially if associated with sepsis or septic shock (B-II).
2. Vancomycin is recommended for empirical therapy in patients with suspected CRBSI (B-II). Teicoplanin is not recommended as empirical therapy, given the existence of coagulase-negative staphylococci with reduced susceptibility to teicoplanin (C-III).
3. Daptomycin can be administered for cases of CRBSI with septic shock (C-III), acute kidney injury (B-III), to patients with recent exposure to vancomycin (>1 week in the past 3 months) (C-III) or if the local prevalence of *S. aureus* isolates with vancomycin MIC $\geq 1.5$ $\mu$g/ml is high (C-III). The local prevalence of *S. aureus* isolates with vancomycin MIC $\geq 1.5$ $\mu$g/ml supporting routine empirical use of daptomycin remains undefined.
4. Linezolid should only be used in patients with contraindications for the previous agents (B-II).

*When should empirical coverage of Gram-negative bacilli or fungi be added?*

The incidence of Gram-negative bacilli (GN)-CRBSI is reported to be 17–25% of all episodes of CRBSI. GN-CRBSI is particularly relevant during outbreaks and
in patients with special conditions, such as spinal cord injuries, femoral catheters, neutropenia and hematologic malignancy, gastrointestinal colonization, prolonged ICU stay, post-operative status or diabetes. In some centers, the predominance of GN-CRBSI has been related to an increase in transplants (solid organ or hematologic bone marrow) and the implementation of bundled strategies for the prevention of CRBSI including the use of chlorhexidine/silver sulphadiazine-impregnated catheters, which preferentially prevent Gram-positive CRBSI. In a recent report, solid organ transplant, prior use of penicillin and hospital stays of more than 11 days were independently associated with a significantly higher risk of GN-CRBSI, whereas, cirrhosis, diabetes and use of quinolones were associated with a higher risk of Gram-positive CRBSI. Femoral catheterization is associated with a higher incidence of CRBSI due to Gram-negative bacilli than at other anatomic sites, so that empirical antibiotic coverage for Gram-negative bacilli has been suggested when CRBSI is suspected in patients with femoral access. No clinical trial has validated the benefits of specific drugs for the management of GN-CRBSI; empirical coverage should be based on local antimicrobial susceptibility data and disease severity.

A prospective study of risk factors for yeast bacteremia found that the rate of Candida spp. CRBSI was significantly higher in femoral catheters than at other catheter sites (16.67% vs. 1.92%; \( p = 0.035 \)). A recent study, however, identified only solid tumors (OR = 3.11; 95% CI = 1.75–5.53), total parenteral nutrition (OR = 2.65; 95% CI = 1.39–5.06) and administration of anti-anaerobic agents (OR = 2.22; 95% CI = 1.03–4.79) as independent variables for Candida CRBSI. In that study, the (1,3)-\( \beta \)-D-glucan (BDG) test was positive in 94.6% (35/37) of Candida spp.-CRBSI patients and 9.4% (10/106) of non-candidal CRBSI cases. For ICU patients, multivariate logistic regression analysis identified severity of illness on the day of candidemia (as measured by the SOFA score) as the only potential risk factor for CRBSI caused by Candida spp.

**RECOMMENDATIONS**

1. Patients with suspected CRBSI should receive empirical antibiotic therapy (in addition to coverage for...
Gram-positive pathogens) to cover Gram-negative bacilli under any of the following circumstances: hemodynamic instability (septic shock), neutropenia or hematologic malignancy, solid organ or bone marrow transplant, femoral catheter in place, a high index of colonization with Gram-negative bacilli or prolonged ICU admission (C-III).

2. Antimicrobial therapy should be adapted to local epidemiology and must include an antipseudomonal agent (i.e., piperacillin-tazobactam, carbapenems, a fourth-generation cephalosporin, aztreonam, quinolones or aminoglycosides) (A-II). Aztreonam and cephalosporins should be avoided in patients with colonization or at risk for extended-spectrum β-lactamase infections (A-I).

3. The need for empirical antifungal therapy in a patient with suspected catheter-related candidemia should be evaluated along with the possibility of catheter removal (A-III).

4. Empirical therapy for suspected catheter-related candidemia should be considered in patients who are hemodynamically unstable with one or more of the following conditions: total parenteral nutrition, prolonged use of broad-spectrum antibiotics, malignancy, femoral catheterization, colonization due to Candida spp. at multiple sites or intense previous anti-anaerobic therapy (C-III).

5. The use of biomarkers (such as 1,3-β-D-glucan) may be useful when considering initiation of empirical antifungal treatment (B-III).

What particular aspects should be considered in the empirical treatment of CRBSI in patients on hemodialysis?

Vascular catheters are the leading source of bacteremia in HD patients. Bacteremia usually develops when the catheter is in use. Catheter salvage should be a priority in these patients.

Conservative management is associated with a higher success rate when a combination of systemic antibiotics and catheter antibiotic lock protocol is used. The microorganisms that cause CRBSI in hemodialysis patients are similar to those observed in other patient populations, although usually with a higher proportion of S. aureus in most series. S. aureus CRBSI is one of the most difficult microorganisms to treat while maintaining a catheter in place due to its propensity to cause septic complications, treatment failure and relapses. S. epidermidis CRBSI, however, has shown excellent results when treated conservatively by combining systemic and local antibiotics during the interdialytic period.

Alternatively, if retaining the catheter is not possible, catheter exchange over a guidewire has been shown to be safe. This approach could lead to higher cure rates for S. aureus infections than treatment based on antibiotic lock therapy. Systemic antibiotics should be administered taking into consideration the PK/PD characteristics of each particular drug for patients with end-stage renal disease or undergoing hemodialysis.

**RECOMMENDATIONS**

1. Conservative management of CRBSI should be attempted with hemodialysis patients. Combining systemic and local intracatheter antibiotics is associated with better results when compared to systemic antibiotics alone (A-I).

2. In patients with a tunneled hemodialysis catheter, guidewire exchange is an alternative, especially when catheter removal is not feasible (C-III).

**Targeted antimicrobial therapy**

Fig. 2 summarizes the pathogen-directed management of confirmed CRBSI.

What is the recommended directed therapy and optimal duration of treatment for CRBSI due to Staphylococcus aureus?

Methicillin-resistant S. aureus (MRSA) CRBSI. The treatment of choice is high-dose intravenous isoaxazolyl penicillin, (i.e., cloxacillin). Cefazolin is an adequate alternative. Treatment with other beta-lactams, including second- and third-generation cephalosporins, has been associated with increased mortality. Likewise, the in vitro activity and clinical results of vancomycin therapy for MSSA have been repeatedly shown to be significantly worse. In patients allergic to beta-lactams, the use of intravenous daptomycin yields comparable results to cloxacillin. Infections caused by methicillin-resistant S. aureus (MSSA) strains with reduced susceptibility to vancomycin (MIC ≥1.5 mg/l, measured by E-test) have been associated with worse outcomes, even when treated with cloxacillin.

Duration of uncomplicated MSSA CRBSI treatment is 14 days, including for patients with intravenous prosthetic devices and negative transesophageal echocardiographic (TEE) findings. Blood cultures should be obtained after 72 h of antibiotic therapy. The management of patients with persistent positive blood cultures and/or no clinical improvement after catheter removal is outlined elsewhere. Duration of treatment for these episodes of complicated CRBSI is 4–6 weeks.

Methicillin-resistant S. aureus (MRSA) CRBSI. Vancomycin is the treatment of choice for MRSA-CRBSI. The vancomycin dose should be adjusted to maintain trough levels of 15–20 mg/l in order to achieve the best predictor of efficacy for this antibiotic in MRSA bacteremia (i.e., AUC/MIC >400). Teicoplanin is a suitable alternative to vancomycin, probably associated with fewer side effects, although serum level concentrations cannot be measured in clinical practice and the optimal dose is not well defined. If the vancomycin MIC is ≥1.5 mg/l, alternative antibiotics such as daptomycin should be considered, although there are no randomized studies available. Combination therapies for complicated MRSA bacteremia have been reported, such as daptomycin with a beta-lactam (i.e., cloxacillin), daptomycin with fosfomycin, and imipenem with fosfomycin. For further information, this panel recommends a guideline recently released by the SEIMC. Duration of treatment for uncomplicated and complicated MRSA CRBSI is the same as for MSSA.

**RECOMMENDATIONS**

1. The treatment of choice for an episode of MSSA CRBSI is cloxacillin or cefazoline (B-I).
Figure 2  Approach to the treatment of a patient with confirmed CRBSI. (1) With the exception of Staphylococcus lugdunensis, which should be managed as for Staphylococcus aureus. (2) Catheter must be removed in patients with septic shock secondary to CRBSI or in patients with intravascular devices. (3) In patients with intravascular devices, foreign bodies (such as articular prostheses) or in whom markers of inflammation persist after catheter removal therapy, antibiotic therapy for 10–14 days is recommended. (4) Cloxacillin or cefazolin are the alternatives for methicillin-susceptible strains. Optimal trough levels of vancomycin for CoNS are not defined. (5) Echocardiography should be done in patients with valvular diseases or in case of persistent bacteremia despite appropriate therapy. (6) Complicated episodes require longer courses of treatment (4–6 weeks). (7) Trough levels of vancomycin should be 15–20 mg/l. (8) Daptomycin is preferred for isolates with MIC for vancomycin > 1.5 mg/l. (9) Combined therapy with an aminoglycoside is discouraged for Enterococcus spp. CRBSI. (10) Optimal trough levels of vancomycin for Enterococcus spp. CRBSI are not defined. (11) Only in immunocompetent patients without septic shock and when the isolate is susceptible to antibiotics that are available for ALT. (12) If metastatic complications have been ruled out. (13) De-escalation from an echinocandin or a lipid formulation of amphotericin B to fluconazole is highly recommended in patients with isolates susceptible to fluconazole, are clinically stable and the catheter has been removed.
2. Patients allergic to beta-lactams should be treated with daptomycin (A-I) or a glycopeptide (B-II).
3. The best antimicrobial treatment for episodes caused by MSSA strains with reduced susceptibility to vancomycin (MIC ≥1.5 mg/l measured by E-test) has not been elucidated. This panel suggests using a combination of cloxacillin and daptomycin when blood cultures remain positive and/or there is no obvious clinical improvement after catheter removal (C-III).
4. Vancomycin is the treatment of choice for CRBSI caused by MRSA (B-II). Teicoplanin may be a valid alternative, especially in cases of serious side effects associated with the use of vancomycin (C-III).
5. Alternatively, patients may be treated with daptomycin, specifically if vancomycin MIC measured by E-test is ≥1.5 mg/l (A-I).
6. Linezolid should only be used in patients when the previous agents are contraindicated (C-III).
7. For both MSSA and MRSA CRBSI, blood cultures should be obtained after 72 h of antibiotic therapy (C-III).

What is the recommended directed therapy and optimal duration of treatment for CRBSI due to coagulase-negative Staphylococcus (CoNS)?

CoNS-CRBSI is associated with a significant increase in duration of hospital stay, although without attributable mortality. As these infections may resolve simply by removing the catheter, some authors suggest that antibiotic therapy is not necessary in immunocompetent patients with no signs of infection and no foreign bodies. If the catheter is removed, uncomplicated CRBSI can be treated with a short course of 5–7 days of antibiotics. In the infrequent case of a strain that is susceptible to methicillin, the recommended antibiotics are a penicillinase-resistant penicillin (i.e., cloxacillin 2 g/4 h) or cefazolin. Vancomycin is the treatment of choice for MR-CoNS CRBSI. Teicoplanin is also a suitable alternative for directed therapy.

10–14 days of antibiotic therapy is recommended for patients with intravascular devices, biomedical devices, or persistent markers of inflammation after catheter removal, although this issue has not been addressed in clinical studies. If for some reason the catheter needs to be retained, antibiotic lock therapy is a further reasonable alternative.

Staphylococcus lugdunensis can cause severe infection, with an aggressive clinical course similar to Staphylococcus aureus infection. For this reason, S. lugdunensis CRBSI should be managed as for S. aureus bloodstream infection.

RECOMMENDATIONS
1. Cloxacillin or cefazolin are the treatments of choice for episodes of CRBSI caused by CoNS susceptible to methicillin (B-I).
2. For CoNS resistant to methicillin, a glycopeptide is the treatment of choice for directed therapy (B-II). Teicoplanin is recommended in the case of serious side effects associated with vancomycin (C-III).
3. The optimal trough concentration of vancomycin for the treatment of CoNS CRBSI is an unresolved issue and this panel cannot issue a specific recommendation (C-III).
4. S. lugdunensis CRBSI should be managed as for S. aureus CRBSI (C-III).

What is the recommended directed therapy and its optimal duration for CRBSI due to Enterococcus spp.?

Enterococcus spp. are becoming an increasingly common cause of CRBSI and represent the fourth leading cause of these infections. For susceptible isolates, ampicillin is the drug of choice. After adjusting for confounders, glycopeptide use is associated with increased mortality in patients with Enterococcus faecalis bacteremia, compared with beta-lactam therapy. There is no information to support the superiority of combination therapy (a beta-lactam plus an aminoglycoside) over beta-lactam monotherapy for uncomplicated CRBSI. For other species of Enterococcus, particularly E. faecium, with a high rate of resistance to ampicillin, vancomycin is the drug of choice. For Enterococcus faecium isolates resistant to vancomycin, linezolid seems to be superior to daptomycin. Duration of treatment is an unresolved issue, but is within the range of 7–14 days.

It is worth mentioning that a recent retrospective cohort study of adults with enterococcal CRBSI showed a lower in-hospital mortality rate for patients whose CVCs had been removed (18.3% vs. 37.9%; p = 0.03). In the multivariate analysis, catheter retention was an independent predictor of mortality (OR = 3.34 [95% CI = 1.21–9.26]).

RECOMMENDATIONS
1. Enterococcal CRBSI should be treated with catheter withdrawal and one active antimicrobial (A-III).
2. Ampicillin is the drug of choice for susceptible isolates (A-II). Vancomycin should be reserved for isolates resistant to ampicillin or cases of beta-lactam allergy. For vancomycin-resistant isolates or severe adverse effects, linezolid is preferred to daptomycin (B-III).
3. There is no evidence that combination therapy is necessary if IE has been properly ruled out (A-III).
4. Despite data suggesting that duration of treatment may be shorter, the standard 7–14 days regimen continues to be recommended (A-III).

What is the recommended directed therapy and its optimal duration for CRBSI due to Gram-negative bacilli?

As stated in the section on empirical therapy, no clinical trials have assessed specific antibiotic drugs in the management of GN-CRBSI. For targeted therapy, the choice should be based on susceptibility results and directed at the narrowest spectrum antibiotic. In this clinical scenario, the principles of antimicrobial stewardship should be applied wisely. There are no studies evaluating the length of antimicrobial therapy for patients with GN-CRBSI. Duration of therapy should be individualized, taking into account clinical factors such as resolution of symptoms or immunological status. Recommended length of treatment is usually no less than 7 days.

RECOMMENDATIONS
1. Directed therapy for GN-CRBSI should be chosen on the basis of the susceptibility results (C-III).
2. The appropriate length of antimicrobial therapy has not been elucidated, although it is recommended to continue therapy for at least 7 days (C-II).
What is the recommended directed therapy and its optimal duration for CRBSI due to Candida spp.?

Echinocandins are currently recommended for empirical therapy in candidemic patients with severe infections.197,198 The decision of whether to continue with an echinocandin or use a step-down therapy to an agent with a narrower spectrum (i.e., fluconazole) is based on several factors: (a) catheter removal; (b) the strain is fluconazole-susceptible; (c) the patient has a good clinical response and is hemodynamically stable; (d) blood cultures have become negative. An open-label, non-comparative study documented de-escalation from anidulafungin to fluconazole as a safe strategy for patients with candidemia.199 In critically ill patients with invasive candidiasis, an observational study confirmed that de-escalation within 5 days is not related to increased day-28 mortality.200 No study has specifically assessed the impact of de-escalation of antifungal treatments in CRBSI caused by Candida spp. Combination therapy is not recommended for Candida-CRBSI.197,198 Removal of an intravenous catheter is an independent determinant of survival in patients with candidemia, especially when the catheter is the source of Candida bloodstream infection or associated with septic shock.210,201-203

Biofilm formation is an important factor in the pathogenesis of CRBSI and the choice of the most appropriate treatment should be guided by differences in the activity of antifungals against Candida biofilms. Liposomal amphotericin B and echinocandins are active against Candida cells in biofilm, while the activity of amphotericin B deoxycholate and azoles is poor.204 In the possible situation with certain types of patient that the catheter cannot be removed for some reason and must remain in place, it is wise to use an antifungal agent with high activity against the biofilm.205-208

Based on the study protocol of relevant clinical trials, the recommended duration of treatment is two weeks (14 days) after the first negative blood culture, so that follow-up blood cultures every other day until blood cultures become negative are helpful to establish the appropriate duration of antifungal therapy.

RECOMMENDATIONS

1. In patients with Candida spp. CRBSI, this panel advocates de-escalation from an echinocandin or a lipid formulation of amphotericin B to fluconazole for susceptible isolates in clinically stable patients who have undergone catheter removal (B-II).

2. The recommended duration of therapy for candidemia without obvious metastatic complications is two weeks after the first set of negative blood cultures (B-III).

3. In candidemia, all intravascular catheters should be removed if at all feasible (B-II), particularly in patients with septic shock and when Candida CRBSI is suspected (B-III).

4. If a catheter that is the source of a Candida bloodstream infection cannot be removed for any reason and remains in place, an antifungal agent with high activity against biofilms should be used (i.e., an echinocandin or liposomal amphotericin B) (A-II).

What is the recommended directed therapy and its optimal duration for CRBSI due to nontuberculous mycobacteria (NTM)?

CRBSI and/or sepsis are the most common healthcare-associated types of infection due to pathogenic rapidly growing mycobacteria (RGM) in both immunosuppressed and immunocompetent patients. The organisms may not only cause mycobacteremia, but can also present as local wound exudate from an exit site or tunnel infection. The most commonly recovered RGM species or groups include M. fortuitum, M. abscessus, and the M. mucogenicum group.209-211 Both short- and long-term catheters should be removed in CRBSI due to mycobacteria.

The duration of treatment for NTM CRBSI varies, but is usually at least 6–12 weeks to prevent relapse.212,213 In leukemic children, recent studies suggest that systemic infections due to mycobacteria may require up to 2 years of therapy, even if the catheter is removed. The prognosis is excellent if the catheter is pulled in addition to systemic antibiotic therapy over an extended period.

RECOMMENDATIONS

1. The treatment for CRBSI caused by NTM involves removal of the infected catheter (B-II) followed by combination antimicrobial treatment appropriate for the species involved (B-III).

2. The duration of treatment for NTM CRBSI should be 6 to 12 weeks to prevent recurrence of infection and the development of septic metastases (B-III).

Should antimicrobials for CRBSI be administered intravenously for the entire course of treatment?

The efficacy of treatment for CRBSI depends on the following factors: (a) early or prompt removal of the catheter; (b) documentation of bacteremia, identification of the causative organism and its susceptibility pattern; (c) clinical response during the first 48–72 h of empiric therapy; and (d) development of complications. All patients with CRBSI require initial intravenous antimicrobial therapy. The above factors should determine duration of treatment and whether to use a sequential treatment or switch to the oral route. A randomized open trial compared oral combination therapy with a fluoroquinolone plus rifampicin (IV for 24 h, but switched to the oral route as soon as possible) with standard parenteral therapy (fluclorafoxacin or vancomycin) for bacteremia or deep-seated infections caused by S. aureus or catheter-related bacteremia due to drug-susceptible CoNS. Approximately 40% of infections were CRBSI: two-thirds due to S. aureus and the rest to CoNS. Clinical and bacteriological cure rates were similar in both groups, although the median length of hospital stay was significantly shorter in the oral group.214 A recent study demonstrated that oral linezolid as monotherapy or combination therapy, mostly with rifampicin, is a valid alternative to intravenous therapy for patients with Gram-positive infections, although the number of CRBSI cases was low. Interestingly, none of the patients with CRBSI needed to be readmitted to hospital due to infection or to revert to intravenous antibiotic treatment.215

Clinical trials evaluating echinocandins allowed a swift change to oral fluconazole after 7–10 days of intravenous therapy, although specific analyses of the outcome of the Candida CRBSI subgroup are not available.216-218 A recent non-comparative trial of candidemia, in which approximately 50% of the episodes were CRBSI, showed that an early step-down strategy from intravenous anidulafungin to
oral azole therapy after 5 days was effective and safe and reduced the length of intravenous treatment.199

No specific information is available about the use of oral therapy for Gram-negative CRBSI. Sequential oral therapy can be considered for clinically stable patients without metastatic complications and with negative blood cultures after onset of treatment and removal of the intravenous line.

**RECOMMENDATIONS**

1. Sequential oral therapy can be considered in clinically stable patients without metastatic complications and with negative blood cultures after onset of treatment and removal of the intravenous line, if a therapeutic option with high oral bioavailability is available (A-II).

2. In uncomplicated CRBSI caused by fluoroquinolone-susceptible staphylococci, initial intravenous antibiotic treatment may be switched to high-dose oral fluoroquinolones plus rifampicin in order to complete the course of antibiotic therapy if the patient is clinically stable and clearance of bacteremia is documented. Linezolid could be an option if the microorganism involved is fluoroquinolone-resistant (A-II).

3. In uncomplicated CRBSI caused by fluoroquinolone-susceptible Gram-negative bacilli, initial intravenous antibiotic treatment may be switched to high-dose oral fluoroquinolones in order to complete the course of antibiotic therapy if the patient is clinically stable and clearance of bacteremia is documented (A-II).

4. A step-down from an echinocandin or lipid formulation of amphotericin B to oral fluconazole is safe and effective (C-III).

**Conservative treatment: Antibiotic Lock Therapy (ALT)**

*When is conservative management with antibiotic lock therapy recommended?*

Whenever a conservative treatment is chosen, antibiotic lock therapy should be combined with a systemic antimicrobial. The patient should also be in a stable condition and the causative microorganism considered of low virulence, i.e., CoNS. Metastasis or local septic complications should be excluded before initiating conservative treatment. Table 4 summarizes the indications for catheter removal that make antibiotic lock therapy impossible. Lock therapy involves filling the catheter lumen with a mixture of an anticoagulant and a highly concentrated antibiotic or antiseptic, and temporarily stopping the catheter from flushing. There is no complete agreement at present about the choice of drugs, the duration of each lock period or local treatment.219 The first randomized, placebo-controlled trial220 included only CRBSI from long-term VADs, whether tunneled or totally implanted, and compared an antibiotic lock solution containing vancomycin and ceftazidime with placebo, in addition to parenteral antimicrobial treatment in both arms. 174 patients developed bacteremia, 85 of which were catheter-related and 44 patients met the criteria for the modified intention-to-treat analysis. Failure to cure CRBSI occurred in 33% of patients in the antibiotic lock arm and 57% in the placebo group (HR = 0.55, p = 0.10). The study failed to show statistically significant differences and had to be prematurely stopped due to enrolment difficulties. An open, retrospective and prospective non-comparative study of antibiotic lock therapy with vancomycin plus ciprofloxacin or amikacin for 7–16 days showed an 82% cure rate.172 A prospective non-comparative study of tunneled hemodialysis catheters causing bacteremia combined systemic antimicrobial therapy with lock therapy and cured 40 of 79 patients.221 When compared with the author’s own historical series of patients treated with systemic antibiotics and immediate catheter withdrawal, salvage therapy was not associated with increased complications or long-term differences in survival.

**RECOMMENDATIONS**

1. Conservative treatment should not be prescribed for patients with metastatic or local septic complications (A-II).

2. The use of lock therapy added to systemic antimicrobial agents is systematically recommended for infected catheters that fulfill the criteria for catheter retention: the patient is stable, and the microorganism involved is considered to be of low virulence (i.e., CoNS) (A-I).

3. In stable patients without local or systemic complications, conservative treatment may also be attempted for enterococci, corynebacterium (except Corynebacterium jeikeium) and Gram-negatives (consultation with an ID expert is suggested in such cases) (C-III).

4. The use of an antibiotic lock does not preclude the need for systemic antimicrobial therapy (A-I).

**What antibiotics and concentrations of antibiotic lock solutions are recommended?**

The ideal antibiotic for the conservative treatment of CRBSI should have the following characteristics: (1) high activity against biofilms (ability to penetrate and disrupt the biofilm); (2) able to achieve high concentrations (100–1000 times the MIC of planktonic cells); (3) prolonged stability at room temperature over several days (enables prepared solutions to be stored and the antibiotic lock to be replaced every 24–72 h); (4) compatibility with anticoagulants; (5) safety; (6) low potential for resistance; and (7) cost-effective.222-224

There are no randomized studies comparing the effectiveness of different antibiotics used for antimicrobial lock therapy (ALT). The data derive from very heterogeneous observational studies. This is a summary of the most commonly used published evidence.

Vancomycin is probably the most widely used antibiotic for ALT at concentrations ranging from 2000 to 20,000 mg/l, with 2000 mg/l being the most commonly used since the drug precipitates at 10,000 mg/l. Vancomycin at 2000 mg/l is stable at 37 °C, and can be combined with heparin at 20–100 IU/ml and 4% sodium citrate, as well as with other antibiotics such as ciprofloxacin, gentamicin, amikacin and ceftazidime, which facilitates the treatment of polymicrobial infections. In terms of efficacy, 2000 mg/l vancomycin has been shown to cure 77–93% of infections caused by CoNS. 

Teicoplanin has been used at concentrations between 5000 and 20,000 mg/l, the most commonly used being 10,000 mg/l. It remains stable for 96 h, with and without associated heparin. It can combine with 100 IU/ml heparin, and with amikacin and gentamicin for polymicrobial infections. Teicoplanin 10,000 mg/l has shown superior efficacy to vancomycin 2000 mg/l.

Daptomycin has been used at concentrations of between 3500 and 5000 mg/l. Ringer’s lactate should be added to the solution. The solution remains stable with and without heparin for 96 h, and can be combined with heparin 100, 400 and 5000 IU/ml and 4% sodium citrate (daptomycin 5000 mg/l), as well as with 25% ethanol. In a study of 13 cases, daptomycin 5000 mg/l achieved an 85% clinical cure rate.

Ciprofloxacin at 2000 mg/l has been used for the treatment of infections caused by Gram-negative bacilli, including Pseudomonas spp., reaching success rates of 95% in selected populations. The solution remains stable for 10 days at 37 °C. It precipitates with heparin, but maintains its efficacy.

Amikacin has been widely used at concentrations of between 1500 and 60,000 mg/l, the most frequently used being 2000 mg/l. It can be administered with heparin and its efficacy is high, above 90%.

Other antibiotics used as ALT for the conservative treatment of CRBSI are gentamicin (2000–5000 mg/l), cefazolin (5000–10,000 mg/l), and ceftazidime (500–10,000 mg/l).

**RECOMMENDATION**

1. The most frequently used antibiotics for conservative treatment of CRBSI using ALT are vancomycin 2000 mg/l, teicoplanin 10,000 mg/l, daptomycin 5000 mg/l, ciprofloxacin 2000 mg/l, and amikacin 2000 mg/l (B-I).

**How should antibiotic lock therapy be performed?**

Lock solutions reported in the literature with potential use in clinical practice are described in Table 5. Although many published studies on the effectiveness of ALT are available, very few describe the technique in detail.

**ALT preparation and storage.** The solution should be prepared under sterile conditions, ideally in the Pharmacy Service. These solutions have prolonged stability and can be prepared every 3–7 days and stored at 4 °C until required for use (Table 6).

**Volume of the lock solution.** Most studies use between 2 and 3 ml in tunneled catheters and 3–5 ml in totally implantable ports. However, considering the great variability of catheters used, the exact catheter volume specified in the instructions provided by the manufacturer should be instilled.

**Replacement of ALT solutions.** Before using the catheter or replacing the ALT solution, the previous ALT should be removed to prevent the risk of adverse events associated with the rapid infusion of antibiotics at high concentrations and the cleaning of the catheter lumen occurring by entrainment.

**Length of ALT.** The optimal duration of ALT is not known. In most recent studies, ALT was given for 10–14 days, although a shorter treatment duration may be efficacious, especially for Gram-negative infections.

**Frequency of ALT.** The frequency of ALT replacement has not been established. It is usually performed every 24–72 h and adapted to the use and needs of the infected line. In hemodialysis patients, ALT is replaced after each hemodialysis session. If more frequent use of the catheter is needed, the lock is replaced every 24 h.

**Catheter use.** Ideally, the catheter should not be used while the ALT solution is in place. However, for patients receiving parenteral nutrition or those with few or no other venous access options, ALT and catheter may be alternated. In such cases, a minimum of 8–12 h a day is recommended. If the catheter has more than one lumen, all should be treated.

**Systemic treatment.** Bacteremic patients should be treated with systemic antibiotics for a period of 7–14 days. This period may be shorter for CoNS infections.

**RECOMMENDATION**

1. An ALT solution should be prepared under sterile conditions. It should be infused after removing the previous dose and the exact volume of the catheter lumen should be infused. The recommended duration of ALT is 10–14 days. The ALT solution must remain in the catheter lumen for a minimum of 12 h a day and should be replaced every 24–72 h (B-I).

**What non-antibiotic substances could be used for lock therapy?**

Apart from the antibiotics described above, other non-antibiotic substances have been used for lock therapy.

Ethanol (with activity against bacteria and fungi) has been used for the prevention of CRBSI in long-term CVCs. In several therapeutic randomized trials, a 70% ethanol lock showed a significant decrease in the rate of CRBSI compared with saline or heparin solutions. It is important to note that these studies also reported severe adverse events, such as flushes, dizziness, doubling of liver enzymes, catheter rupture or thrombosis, leading to interruption of therapy in some patients. Two retrospective studies and one randomized study including more than 100 patients that used 70% ethanol lock therapy for the treatment of

This table is not intended to be an exhaustive list. Since there are no clinical trials using levels of evidence, it reflects only the opinion of experts. Although there is no scientific evidence to make recommendations regarding optimal time duration and replacement of lock solutions, we recommend extending it for 14 days, and also drawing a blood culture through all catheter lumens 72 h after completion of therapy. We also remind users that antimicrobial lock therapy is necessary but not sufficient. Any antimicrobial lock therapy must be accompanied by a systemic antibiotic treatment that will last over time, depending on the pathogen involved.

<sup>a</sup> A conservative treatment is recommended only in the case of coagulase-negative staphylococci. Catheter removal is recommended if S. aureus is involved.

<sup>b</sup> There is insufficient experience to recommend conservative treatment. However, if the patient is stable and bacteremia is uncomplicated, a conservative treatment may be considered.

<sup>c</sup> In the case of *Pseudomonas aeruginosa* and other non-fermenting Gram-negative bacilli (*Acinetobacter* spp, *Stenotrophomonas* spp and so on), there is no clear recommendation for a conservative treatment.

<sup>d</sup> In the case of catheter-related candidemia, it is recommended to remove the catheter. If it is not possible to withdraw it, or withdrawal is postponed, the catheter should be locked.

CRBSI, cure rates were reported in 62–91% of cases with no significant adverse events. 107,251,252

*Tauroloidine*, like 70% ethanol, has been evaluated in several large randomized studies of the prevention of CRBSI. Tauroloidine, mostly compared with heparin, was associated with significant reductions in the rate of bloodstream infections. In a retrospective study of 11 cancer patients treated for CRBSI with a tauroloidine lock, only three relapsed, but were eventually cured with another tauroloidine lock. 253

*EDTA and citrate*. These two chelators are able to disrupt biofilm, thus increasing antimicrobial activity. Several in vitro studies have demonstrated the proven anti-biofilm effect of EDTA alone or in combination with gentamicin or minocycline plus 25% ethanol. Further clinical studies are needed to establish the role of these two substances. 254

**RECOMMENDATION**

1. 70% ethanol and tauroloidine locks might be used for the conservative treatment of CRBSI. However, there is no evidence to advocate for their routine use (B-I).

**What are the criteria for failure of conservative management?**

The criteria for failure of conservative treatment of CRBSI are based on the patient’s worsening clinical condition, persistence of infection, and catheter dysfunction or removal 95,166,172,228,235–257

It does not seem to be ethical to perform a randomized clinical trial about retaining infected catheters for certain critical clinical conditions. Catheter dysfunction
requiring replacement is also considered failure of conservative treatment. In most reports, catheters were removed for ongoing sepsis, defined as persistent fever or bacteremia after 48–72 h of adequate therapy, or if metastatic septic complications like endocarditis or osteomyelitis, or local complications, such as venous thrombosis, septic phlebitis or tunnelitis, occurred. Conservative management is contraindicated for some of these complications, which should be followed by sequential blood cultures drawn both from a peripheral vein and through the catheter to monitor the clinical course of CRBSI.218,235

Definitions of efficacy or failure of conservative management in clinical studies or clinical practice sometimes include late relapse of infection.257

RECOMMENDATION

1. Any clinical condition or catheter dysfunction prompting catheter removal should be considered failure of conservative management (A-I).

Management of local complications

How should insertion site infection be managed?

Short-term catheters (peripheral venous, non-tunneled CVCs and arterial catheters) with erythema, pain, warmth, induration and/or purulent drainage within 2 cm of the catheter exit site should be removed in spite of absence of concomitant bacteremia.25,258 Any exudate at the insertion site should be submitted for Gram staining, routine culture, and fungal culture when assessing immunocompromised patients.25

In uncomplicated infections involving long-term catheters (tunneled CVCs, hemodialysis), defined as absence of fever, positive blood cultures or purulence, cultures of any drainage from the exit site should be obtained, together with peripheral blood cultures.259 Under these circumstances, topical application of an antibiotic ointment at the insertion site may be considered, based on exit-site culture results. If the infection does not resolve or purulent exudate develops, systemic antibiotics should be administered. If clinical signs of infection persist after 48–72 h of appropriate antimicrobial therapy, the catheter should be removed.25,259 The topical application of antibiotic ointment to the insertion site following catheter removal is not recommended.260

RECOMMENDATIONS

1. For peripheral venous catheters, catheter removal is mandatory if there is local pain, induration, erythema or exudate (A-I).

2. For non-tunneled CVCs, the presence of erythema or purulence at the catheter insertion site requires immediate catheter removal (B-II).

3. For uncomplicated exit site infections with long-term catheters, a conservative approach with topical antimicrobial agents should first be attempted. In cases of topical treatment failure, systemic antibiotics should be administered (B-III).

4. Persistence of clinical signs of infection beyond 72 h of conservative management requires removal of the catheter (B-II).

How should tunnelitis be managed?

Tunnel infection in a long-term catheter, other than a hemodialysis catheter, should be managed with catheter removal, drainage and incision, if indicated, and 7–10 days of systemic antibiotic therapy in the absence of concomitant bacteremia or candidemia.25,261 If systemic antibiotics fail, the catheter should be removed. In the setting of tunnel infection with fever, catheter removal is the first option, together with adequate antibiotic therapy.68,262

Taking a conservative approach, failure rates of more than 50% have been reported and, in this case, are associated with increased cost and workload.222,263

RECOMMENDATIONS

1. Patients with tunnelitis not associated with a hemodialysis catheter require catheter removal, incision and drainage, if indicated, and 7–10 days of systemic antimicrobial therapy in the absence of concomitant bacteremia or candidemia (A-II).

2. For tunnelitis without fever in hemodialysis catheters, systemic antibiotic therapy may be attempted first (A-II). In tunnel infection with fever, catheter removal is the first therapeutic option together with systemic antimicrobial therapy (A-II).

3. Tunnelitis conservative management is associated with higher failure rates (B-II).

How should a local infection associated with a port reservoir be managed?

A complicated local infection of a venous access device is defined as infection of the tunnel or port pocket with erythema or induration (more than 2 cm), purulent collection, skin necrosis and spontaneous rupture and drainage. A stitch abscess is a focal area of purulence or redness around a suture. The single offending stitch can usually be removed without further consequences and should not be confused with a port infection.262 Management of a port reservoir infection requires removal of the port, drainage of affected tissues and administration of antibiotic therapy for 7–10 days in the absence of concomitant bacteremia or fungemia.263 Depending on the severity of the infection, the insertion wound may be sutured following removal of the port, and, if there is significant drainage, exudate or purulence, the wound should be left open and packed with iodoform gauze to heal by secondary intention.262 Surgical removal of a venous access port is frequently a challenge to management and is initially avoided. Alternately, it may be possible to salvage the port with a conservative treatment by stopping use of the device and initiating a combination of antibiotic lock therapy and systemic antibiotic treatment.264 Most infections are associated with intraluminal colonization and it is necessary therefore to administer a high concentration of antimicrobial solution to try and sterilize the device.264

RECOMMENDATIONS

1. In the presence of signs of local inflammation at the reservoir pocket, the port must be removed, the affected
tissue drained, and systemic antibiotic therapy started (A-II).
2. If a conservative strategy is the only option, a combination of systemic antibiotics and antibiotic lock therapy should be prescribed, bearing in mind that this approach is associated with a high failure rate (B-II).

**Patient follow-up**

In which patients and when should a follow-up blood culture be taken?

Persistent bloodstream infection is defined as the presence of viable pathogens in the blood after 3 days of appropriate antimicrobial treatment. Persistent bacteremia with certain pathogens has been associated with the development of complications and worse outcomes. Patients with persistent bacteremia due to *Staphylococcus aureus* present higher relapse rates and related mortality within 12 weeks of a bacteremia episode. The most robust predictor of complicated *S. aureus* bacteremia was positive follow-up blood cultures at 48-96 h after the first positive blood culture. In a study in which blood cultures were taken every 3 days following a positive blood culture for *S. aureus*, the rate of septic metastasis for bacteremia lasting <3 days was 5%, increasing to 25% in patients with ≥10 days of documented bacteremia.

Persistent candidemia has also been associated with a high mortality rate. Kim et al. reported that persistent candidemia increased the risk of mortality, with adjusted hazard ratio of 2.5 (95% CI = 1.33–4.72). As antifungal therapy should be continued until 14 days after the first negative blood culture, follow-up blood cultures should be obtained daily until the first negative blood culture.

**RECOMMENDATIONS**

1. Follow-up blood cultures should be taken from all patients with *S. aureus* or *Candida* spp. CRBSI (A-II).
2. In patients with *S. aureus* CRBSI, we recommend that follow-up blood cultures should be obtained every 72 h until the first negative result (A-II).
3. Control blood cultures in CRBSI due to *Candida* spp. should be obtained every 48 h until the first negative blood culture (A-II).
4. For other causative microorganisms of CRBSI and if catheter salvage is attempted, follow-up blood cultures should be obtained 72 h after starting appropriate antibiotic therapy. If persistent bacteremia is documented, catheter removal is required (B-II).
5. It is not necessary to routinely perform follow-up blood cultures in patients with CRBSI due to microorganisms other than *S. aureus* or *Candida* spp. if the catheter has been withdrawn (A-II).

When should echocardiography be performed?

The risk of underlying infective endocarditis in bacteremic patients depends mainly on the etiologic agent causing the bacteremia and the predisposing conditions of the patient. Patients with *S. aureus* bacteremia are at high risk for IE, which is frequently not clinically evident or suspected.

The absence of valvular risk (no valvular disease, either previously or diagnosed at the moment of SAB), together with a clinical and microbiological response (negative blood cultures) to therapy within the first 72 h of catheter removal and initiation of adequate antibiotic therapy were associated with a favorable outcome (absence of complications or relapse) in more than 95% of patients who received treatment for at least 14 days after negative blood cultures. A recent systematic review of 9 observational studies with sample sizes ranging from 98 to 877 patients reported an incidence of 2% to 14% detected by transthoracic echocardiography (TTE) and 14% to 25% by transesophageal echocardiography (TEE). Clinical findings and TTE were poorly predictive of subsequent TEE findings. In a high proportion of cases, IE was not suspected on clinical grounds and 15% of cases were reclassified by TEE.

Currently, 6 studies suggest that, due to the very low risk for IE, TEE can safely be avoided in patients without any of the following risk factors: prolonged bacteremia, hemodialysis, community-acquisition, metastatic foci of infection, immunologic or embolic phenomena, intravenous drug abuse (IVDA), implantable CVC, intracardiac device, prosthetic valve, previous IE or cardiac structural abnormality.

In patients with proven enterococcal CRBSI, the requirement to systematically rule out endocarditis is currently under discussion. Estimates of endocardial involvement vary and are not well addressed in the medical literature. In a recent study of 1515 patients with enterococcal BSI (E-BSI), 69 (4.29%) had enterococcal endocarditis, representing 16.7% of patients with E-BSI who underwent TTE and 35.5% with E-BSI who underwent TEE. A bedside score totalling 12 points for predicting enterococcal endocarditis was developed, the NOVA score, based on the number of positive blood cultures, origin of the bacteremia, prior valve disease and the auscultation of a heart murmur. A NOVA score of less than 5 points, which corresponded to 14 to 27% of patients with enterococcal bacteremia, identified a subgroup at very low risk for enterococcal endocarditis who could avoid TEE.

The incidence of endocarditis in patients with candidemia has been assessed less frequently. In a recent study, endocarditis was detected in 2.9% of patients with candidemia using TEE and in 11.5% undergoing TEE.

**RECOMMENDATIONS**

1. TEE should be performed in the vast majority of patients with *Staphylococcus aureus* bacteremia. TEE is not necessary or can be delayed in patients without the following risk factors: prolonged bacteremia, hemodialysis, metastatic foci of infection, IVDA, implantable CVC, intracardiac device, prosthetic valve, previous IE or cardiac structural abnormality (A-II).

2. The need for TEE in episodes of CRBSI caused by other pathogens should be individualized. This panel considers that IE should be ruled out in all patients with persistent bacteremia (or fungemia) (C-III). *Enterococcus* spp. and *Candida* spp. pathogens are associated with a high risk of developing endocarditis.
What is the diagnosis and management for suppurative thrombophlebitis?

Suppurative thrombophlebitis refers to venous thrombosis associated with infection and bacteremia. The pathogenesis of catheter-related thrombosis results from the activation of coagulation pathways by the foreign material in the bloodstream, vascular endothelial damage and endothelial cell activation. Infection may also stimulate thrombus formation by aggravating coagulation abnormalities. The presence of a thrombus mass around the catheter increases the risk for microbial colonization and bacteremia. CRBSI and thrombosis appear therefore to have a bidirectional relationship.

Suppurative thrombophlebitis combines the signs and symptoms of infection from the thrombosis with the dysfunction of the involved catheter. Microbiological and radiologic tests are necessary to confirm the diagnosis. Thrombosis should be confirmed by ultrasonography (70–100% sensitivity and 93% specificity), high-resolution computed tomography or phlebography. Limited experience with magnetic resonance imaging suggests that it may also be useful in the diagnosis of thrombophlebitis. Recent data indicate that a proactive search for thrombosis in the setting of suspected CRBSI is a safe and effective strategy that enables the catheter to be preserved in neutropenic patients if thrombosis is ruled out.

Management of thrombophlebitis requires catheter removal, prolonged antimicrobial treatment of at least 4–6 weeks, surgery (drainage of abscess and/or venous resection) if a collection is detected or the clinical response is not achieved, and thrombus treatment (anticoagulation or even thrombolytic therapy). Venous resection has not been shown to be superior to conservative management (including involvement of superficial veins). There is insufficient clinical evidence available to support the use of systemic anticoagulation, while systemic thrombolysis has only been used in specific cases.

Follow-up of thrombophlebitis should include clinical data, sequential ultrasonography and possibly biomarkers. Procalcitonin (PCT) will probably be more effective for detecting non-responding CRBSI potentially complicated by the associated thrombophlebitis, in which case urgent catheter removal would be required.

RECOMMENDATIONS

1. Suppurative thrombophlebitis should be ruled out in all episodes of CRBSI with persistent bacteremia (A-II).
2. Confirmed diagnosis, mainly by ultrasonography, should be followed by catheter withdrawal, prolonged antibiotic treatment and an individualized assessment of the need for anticoagulation (A-II).

When can a new catheter be inserted?

There is no scientific evidence indicating how long the patient should wait before a new catheter can be safely inserted after an episode of CRBSI. The placement of a new catheter will obviously be determined by the need for vascular access. Patients with short-term catheters for vital continuous infusion medications usually require immediate insertion of a new catheter. If it is feasible to wait, PCT may be useful for monitoring the response to therapy. In a small prospective study including 26 patients with CRBSI, a serum PCT concentration of >1.5 ng/ml on day 3 of therapy was associated with lack of response to therapy (sensitivity 70%, specificity 68.7%; p = 0.028), while a decrease in serum PCT concentrations of at least 1.00 ng/ml from day 1 to day 2 and of 0.30 ng/ml from day 2 to day 3 indicated response to therapy (p = 0.037 and 0.017, respectively).

The clinical situation of patients with long-term catheters, implantable venous access catheters (IVAC) or tunneled catheters may allow for a time interval before a new catheter is placed. Experts recommend waiting for resolution of clinical signs or even microbiological eradication (negative blood cultures). The only available study is a small case-control evaluation, which showed no differences between removal with simultaneous reimplantation in 13 patients and delayed reimplantation (mean 14 days) in 21. There were two cases of re-infection in the simultaneous reimplantation group (15.4%) and one case in the delayed reimplantation group (4.8%). Non-randomized studies of hemodialysis-associated CRBSI have shown heterogeneous results.

RECOMMENDATIONS

1. Although there is a clear lack of scientific evidence, it seems advisable to wait, if feasible, before placing a new catheter after an episode of CRBSI. The waiting period should be determined by the resolution of signs and symptoms. If a patient urgently needs vascular access, a catheter should be inserted without delay (C-III).
2. Insertion of a new catheter after a diagnosis of CRBSI is always possible if the patient’s clinical condition dictates the need for a new vascular access (A-III).
